In convulsive diseases the pia mater and the whole brain become highly injected more as a consequence of the impeded circulation caused by the struggles of the patient interfering with the due exercise of the respiratory movements, than as the cause of the convulsions. Indeed, there seem good grounds for believing that convulsions are more frequently caused by a deficient supply of blood to the brain than by a superabundant flow of it to that organ.

The pia mater is the seat of the principal morbid deposits which affect the brain. Of these tubercle is among the most common; it most frequently occurs on the surface of the convolutions; but it may be found wherever the pia mater exists, either in the interior or on the outside of the brain. It occurs less frequently on the pia mater of the cerebellum than in any other situation.

The tubercular deposit in the pia mater commences by the developement of minute granulations of a grey, clear, or semi-transparent material. These are deposited close to each other over a greater or less surface, forming a group, and several such groups may be formed near each other. After a time this grey material is changed into a yellow granular matter, which is sometimes enclosed in a cyst.

Tubercular matter originally deposited on the surface of the pia mater in the sulcus of a convolution may have the appearance as if it had been formed in the substance of the brain. The sulcus is obliterated, and the tubercle, enlarging towards the brain, becomes, in a short time, surrounded by cerebral matter.

Sometimes tubercle deposited in some part of the pia mater excites inflammation in the pia mater and arachnoid immediately near it,—*tubercular meningitis;* and this may affect more or less of the substance of the brain in its vicinity, causing red softening.

Cerebral tubercle is seldom or never alone. Other organs of the body are almost invariably affected at the same time, the lymphatic or the mesenteric glands, or the lungs. It is most commonly found in children, and it is not improbable that it may lie dormant for years until roused to action by some newly-developed morbid excitant.

Connected with diseased states of the membranes of the brain, it should be remarked that in many instances acute affections of the membranes of the brain find their point of departure in inflammation of the sinuses. The sinus which is most frequently inflamed is the lateral; the inflammatory state of this spreads to the neighbouring arachnoid and pia mater, and induces all the consequences of a primary meningitis.

Of the abnormal states of the brain.—The abnormal conditions of the brain may be considered under the heads of — 1, *congenital;* 2, *acquired or morbid.*

1. *Congenital abnormal conditions.*—A total defect of the brain is found in that state in which the head is wanting *(Acephalia)*; and also where there is deficiency of the parietal bones of the cranium, the occipital, temporal, sphenoid, and frontal being present in an imperfect state, and there being also, in general, spina bifida of the upper cervical vertebræ, there is a deficiency of a considerable portion of the encephalon, the medulla oblongata or a portion of it being alone present *(Anencephalia).*

The acephalic state is very frequent. It is always associated with complete or nearly complete absence of the cranial bones, and frequently more or less of those of the spine. In some the trunk and extremities are perfect, but in very many there are deficiencies to a greater or less degree in the formation of these parts.

In anencephalia there is a defective state of encephalon, but not an absence of it; and it seems highly probable that this condition is due, not so much to an original arrest of developement as to the occurrence of an hydrocephalic state at an early period of intra-uterine life, the accumulated fluid breaking down the newly formed nervous matter, which wants the support of the cranial bones.

The extremest degree of this defect is when a large portion of the cranial bones is wanting, and also when there is a large fissure in the spine. In other cases the spinal fissure does not exist. The cranium is largely open on its posterior and superior aspect, the head thrown back, the neck very short and thick, the eyeballs very large and prominent, and the mouth partially open, giving to the features a very hideous expression.

The hollow of the base of the cranium is, in these cases, filled up by a red, soft, highly vascular substance, continuous with the pia mater of the spinal cord. This, in general, appears to be nothing more than the cranial pia mater, which has collapsed into this state by the destruction of the nervous matter, and in which sometimes small masses of nervous matter may be discovered here and there. It is covered by a smooth membrane, which may be an imperfect arachnoid. In some instances, however, the tumour is of considerable size, more voluminous, according to Geoffroy St. Hilaire, than even the normal brain. It is disposed in lobes, which resemble somewhat those of the brain, and which sometimes contain a considerable quantity of serum.

In less degrees of this condition the cranial bones are more developed, the skull is less open, and the brain and its membranes exhibit a greater degree of perfection. In all the cases water is accumulated in the cerebral cavities. The following case quoted from Penchienati by Breschet in his article *Anencephalie*, in the Dictionnaire de Médecine, illustrates the appearances in a by no means advanced stage of the deformity. The subject was a girl which had lived three days. The corpora striata, optic thalami, were present with the hemispheres. The lateral and third ventricles were greatly enlarged. The tubercula quadrigemina retaining their vesicular condition were likewise present, and also the pineal gland. These parts presented at the superior part of the cranium a red eminence which was uncovered by the skin.

In some cases where the degree of openness of the cranium is reduced to a fissure, in front or behind, a tumour is found protruding through either fissure, consisting of the brain, imperfectly developed, inclosed in its membranes. This condition is frequently combined with a greater or less extent of spina bifida.

The partial deficiencies of the brain itself are infinitely various. Those parts which are most frequently either altogether absent or imperfectly developed, are those which are not essential to the production of the organic vital phenomena. The commissures are very frequently wanting, the smaller ones oftener than the larger, such as the corpus callosum and the pons Varolii. The hemispheres of the brain are frequently very imperfectly developed. The medulla oblongata and mesocephale rarely exhibit any material imperfection.

In all cases of idiotcy there is a manifest imperfection in the developement of the brain. This is sufficiently plain to the most superficial observer from the small size of the head which is so frequent a character of this state, and which is more especially remarkable in adult life, where the developement of the cranium by no means keeps pace with that of the rest of the body.

As an example of the class of changes which take place in the brains of most idiots, I shall describe the appearances observed in the brain of an adult idiot which I examined in October, 1844.

On the upper surface of the brain the convolutions were not developed; the surface of both hemispheres was perfectly smooth. The fissure of Sylvius was very deep and well marked, extending upwards and backwards; at its posterior extremity there was a slight puckering indicating a feeble developement of the insula of Reil.

A few fissures and imperfectly developed convolutions were found upon the inferior surface of the middle lobe, as well as upon the lateral and inferior surfaces of the anterior lobe.

The olfactory fissures were perfect but very small; the olfactory nerves appeared natural.

The optic nerves were natural but small.

The tuber cinereum was large and well developed.

The corpora mamillaria appeared to be fused together along the median line.

The pons Varolii very narrow from before backwards; the groove which passes along its middle was imperfect.

The corpus striatum was exceedingly small, and the groove between it and the optic thalamus was greatly increased in size. The tænia semicircularis was large.

The convolution of the corpus callosum was very imperfectly developed. The hippocampus major was very small, and there could scarcely be said to be any trace of the hippocampus minor.

The fornix was well developed, as was also the corpus callosum. The longitudinal tracts on the surface of the corpus callosum were also well developed.

The pineal gland was large and situate very far forwards, corresponding very nearly to the middle of the optic thalamus. The quadrigeminal tubercles seemed imperfectly developed, and the distinction between them was badly marked.

The optic tract was small, but natural in its connections. The cerebellum was well developed: its laminæ seemed natural. The lateral ventricles were large and rather dilated. The entire brain, after having lain in spirits for some days, weighed 1 lb. $4\frac{1}{4}$ oz. avoirdupois.

In some instances the hemispheres of the brain are fused together, there being little or no trace of a longitudinal fissure to separate them. This condition occurs generally in the Cyclopic monsters, or in monsters in which there is a total absence of the organs of vision. Where there is this singleness of brain there is also sometimes a fusion of the corpora striata and optic thalami of opposite sides together.

A total absence of all the transverse commissures of the brain constitutes, as Rokitansky observes, the opposite condition to that just detailed.

Idiotcy results from any change which impairs to a material extent the structure of the hemispheres of the brain and of the fibres by which they are connected to each other, as well as to the other parts of the encephalon. All the recorded instances of dissections of the brains of idiots shew that the evil consists in such an impairment of the hemispheres and their convoluted surface as must have materially prevented their proper action. This may have begun in intra-uterine life or in infancy. The brain of infants at birth is far from being fully formed, and that part of it which is imperfectly developed is that upon which depends the manifestation of mental actions, namely, the hemispheres of the brain and of the cerebellum; the other parts, which are mostly concerned in physical nervous actions, are sufficiently perfect, being, however, generally small from the influence of the deficiency of the hemispheres.

Hypertrophy of the brain would occasion idiotcy, just as well as atrophy or imperfect developement of that organ (*agenesie*). Well-marked cases of idiotcy resulting from the former cause are, however, as far as I know, yet wanting in medical records.

When there is a deficiency in any part of the cranial wall, a protrusion of a greater or less portion of the brain takes place—this constitutes *hernia cerebri* or encephalocele. It is in point of size proportionate to the size of the opening in the cranium. The tumour is covered externally by the common integuments, and the displaced portion of the brain pushes before it the dura mater and the other membranes of the brain.

The most frequent situation for hernia cerebri is in the occipital region of the head near the middle line, and next in point of frequency somewhere on the median line, where the bones of opposite sides remain for so long a time disunited: near the great fontanelle is a frequent site of a protrusion; sometimes it takes place on the side of the skull in the temporal region, or at the root of the nose. Such cases, however, are rare.

2. *Morbid conditions of the brain.—Hypertrophy.*—The examples of hypertrophy of the brain which are on record are not numerous, and it is difficult to attribute the appearances, which are said to indicate this condition, to a mere increase in the nutrition of the organ. Adopting the term, however, in deference to the high authorities who have applied it, it may be stated that the anatomical characters of a hypertrophic brain are as follows:—

The brain appears too large for the skull; on the removal of the calvaria the dura mater seems perfectly tense and filled by the brain; it appears thinner and more transparent than is quite normal, and there is no trace of fluid in the subarachnoid space.

The hemispheres are large, and their convolutions lie closely packed beside each other, and flattened. The ventricles of the brain are small, exhibiting the same condition as the fissures between the convolutions. The surface of the arachnoid as well as of the intra-ventricular eminences is dry or nearly so.

The substance of the brain is universally firm, and cuts somewhat like cartilage; it is exsangueous, the principal accumulation of blood being in the pia mater. The colour of the grey matter becomes so changed as to be scarcely different from the white.

It is as yet uncertain what is the precise change which the brain undergoes in this condition. We know that there is an increase of substance, but whether that be an increase in the normal *size* of the fibres and vesicles of the two varieties of nervous matter which are found in the brain, or in their *number*, or whether it be a deposition of new material, with or without increase in the size or number of the elementary parts of the organ, has yet to be determined by microscopical examination.

It is most probable that the disease consists not merely in an increased, but also in a perverted nutrition, and that new material is deposited between or in the proper anatomical elements of the brain.

In some instances there is, along with the signs of increased nutrition in the brain, evidence of a similar condition of the cranial walls. The bones of the skull are, in such cases, much thicker than usual. In others, however, the bones seem to yield under the pressure from within, and they become thin, and more or less transparent in parts.

There appear to be two classes of cases in which an hypertrophic state of brain occurs. In one class the functions are carried on well, and the only sign of the morbid change is derived from the undue enlargement of the head, which becomes almost too large for the body, and too heavy for the muscles of the neck to support conveniently; in the other there may or may not be enlargement of the head, but there are marks of cerebral disturbance in more or less dullness of intellect, and in the frequent recurrence of epileptic fits.

Dr. Watson has placed upon record two instances of this enlargement of the brain's substance which are highly interesting and will serve to illustrate the varieties above alluded to.

One case was that of a young woman æt. 19. Her countenance was sallow, lips pale. She complained of pain in her chest and limbs, of great and increasing debility and wasting, and of nightly perspirations, and she was subject to attacks of epilepsy. She died in a prolonged epileptic paroxysm. The following appearances were observed at the post-mortem examination.

"When the surface of the brain was exposed by the removal of the skull-cap and dura mater, it was observed that the convolutions were remarkably flattened, so that the little furrows between them were nearly effaced, and the surface of the arachnoid membrane was perfectly dry. These are not very unusual, although they are unnatural appearances. I had often seen such before; and I ventured to say we should find some cause of strong pressure in the central part of the brain, effusion of serum into the ventricles, or a large extravasation of blood. But to my great surprise, and much to the discredit of my prophecy, we found nothing of the kind. The ventricles were even smaller than natural, and contained scarcely any moisture. The skull-cap was afterwards examined, and the bone was found to be uncommonly thick, dense, and heavy; and its inner surface without being rough was very irregular." The state of the bloodvessels of the brain was not noticed. It is to be regretted likewise that the weight of the brain has not been stated, for it is obvious that a gradual and pretty uniform diminution of the cranial cavity by the thickening of the bone might have produced the flattening and condensation of the brain described.

A second case recorded by Dr. Watson occurred in the practice of the late Dr. Sweatman. The patient was a little boy two years old; his head had been gradually increasing from the age of six months until it had become so large as to prevent the child from continuing long in the upright posture. The boy was active and lively although thin. He never had any convulsion, but occasionally seemed uneasy, and then would relieve himself by laying his head upon a chair. He had never squinted, nor was he subject to drowsiness or startings during sleep, and his pupils contracted naturally. His appetite was good, and all the animal functions were properly performed. The head measured from ear to ear twelve inches, from the superciliary ridges to the occipital thirteen inches, and in circumference twenty-one inches. The brain was sound. The convolutions were distinct and retained their shape. The surfaces of the medullary matter, exposed by different sections, presented very unusual vascularity.*

In this case the yielding of the cranial walls prevented compression of the brain, whilst it admitted of the growth of the organ within. Hence, no doubt, the absence of any symptoms of compressed or irritated brain.

Hypertrophy of the brain sometimes coexists with hydrocephalus, and is congenital, and prevents by the great size of the organ the developement of the cranial bones. (Otto, Rokitansky.)

Hypertrophy may affect only particular parts of the brain, as the optic thalami, the pons, and the medulla oblongata, instances of which have been placed on record.

Atrophy of the brain.—At the advanced periods of life we generally meet with more or less of wasting of the brain, resulting from a change in the nutrition of that organ which it experiences in common with all other organs, and which is only the natural result of the progress of age. It is remarkable, however, how much more of this *senile atrophy* is observed in some individuals than in others.

In cases of epilepsy of long standing I have invariably noticed wasting of the brain, affecting chiefly the convolutions, or sometimes the corpora striata, optic thalami, &c. The brain wastes likewise in cases of long-continued intemperance, the patient generally dying of delirium tremens. In such instances all parts of the brain waste, but the convolutions experience the most marked change.

The following are the marks of an atrophied state of brain. There is a considerable quantity of fluid in the subarachnoid cavity, indicating an increase in the interval between the surface of the brain and the interior of the skull. The brain has a shrunk appearance. Its texture feels firm, and in cutting the knife grates against it as in cutting cartilage. In point of colour the grey matter is frequently extremely pale, and scarcely to be distinguished from the adjacent white substance; in some instances, however, it is of a dark brownish hue. In all cases the layer of grey matter which covers the convolution is much less deep than is natural. The convolutions are evidently shrunk, and the sulci between them have greatly increased

* Lectures on the Practice of Physic, vol. i.

in width. The white substance of the brain has increased in density, and in the transverse section several vessels are cut across, the section of which occasions numerous bloody points upon the surface of the centrum ovale. The corpora striata, optic thalami, pons, and medulla oblongata are all obviously shrunk and firm in consistence.

In several instances of persons long bedridden, I have noticed a shrunk state of the cerebellum, with or without atrophy of the cerebrum. The layers of white matter in the cerebellar laminæ look particularly small; and in the section the white layer seems to shrink in within the fold of grey matter in which it is involved.

As a constant accompaniment of the wasted brain, we find a more or less opaque condition of the arachnoid membrane, with considerably enlarged Pacchionian bodies. The ventricles of the brain, too, are generally wide and contain a good deal of fluid. There is also very frequently a diseased state of arteries, atheromatous or ossific deposits being scattered freely amongst those, which form the circle of Willis, and their principal branches.

Atrophy of particular parts of the brain is of not unfrequent occurrence, either in cases where particular nerves are atrophied, as the optic nerve, inducing atrophy of the opposite optic tract or of that of the same side, and of the quadrigeminal bodies on the side of the wasted tract; or where from previous disease of a portion of the brain the remainder of that part has wasted—as wasting of the corpus striatum from the previous existence of a small clot in it, or of a red softening.

Softening. — One of the most common changes of structure in the brain is *softening*. This is of two kinds, namely, white softening, or that without discoloration, and red softening, or that with discoloration.

White softening.—The anatomical characters of the true white softening may be thus described. The diseased portion has diminished considerably in its consistence; if it be gently rubbed with the edge of a knife it becomes obviously disturbed by an amount of friction which would produce no change upon the surface of a healthy brain; a stream of water directed upon it, even with slight force, is sufficient to break it up and separate as well as rupture its constituent fibres, while a similar stream directed against a neighbouring healthy portion produces little or no effect upon it. When examined by the microscope, its constituent fibres appear to have undergone no change but that of consistence; they exhibit varicosities, more numerous than usual, nor can any products of inflammation, or any other abnormal material, be detected among them. The bloodvessels are empty and pale. The colour is very commonly that of cream, sometimes a little more yellow.

This form of softening occurs chiefly in old persons, in whom the arteries of the brain have been more or less ossified, or in whom the vessels leading to the seat of softening have been so diseased as materially to interrupt or diminish the quantity of blood flowing to the part. It has occurred after ligature of the common carotid artery, as must be inferred from the numerous cases of hemiplegic paralysis after this operation, on the side opposite to that of the tied artery; and I have myself recorded a remarkable example in which it was produced throughout nearly the whole hemisphere of the brain by the plugging of the common carotid artery by a dissecting aneurism.*

Any condition of the arteries of the brain, or of the general system, which may impair the nutrition of the brain, is favourable to the production of this form of softening. I have seen instances of it after inveterate contamination of the system by lead, in house-painters, who have had epileptic seizures before death, chemical examination shewing that the nervous matter of the brain contained lead in considerable quantity. It also occurs in persons dead with cerebral symptoms, epilepsy, coma, &c., in Bright's disease of the kidneys.

This softening frequently surrounds apoplectic clots, and in such cases is most probably the precursor of the apoplectic effusion. Frequently small apoplexies are found throughout a patch of softening of this kind, and sometimes the effused blood is infiltrated throughout the softened part to a great extent, and puts on an appearance which has been likened by Rostan and many others to one of the ecchymosed spots which are seen in scurvy.

A colourless softening is found in hydrocephaloid brains. This is probably due to an arrest in the nutrition of the organ, in consequence of which that condition of it which belongs to infancy (when a much larger quantity of water enters into its composition than in the later periods of life, and when the brain-substance is naturally very soft) becomes unduly developed, and water accumulates in the substance as well as in the cavities of the brain. The softening under these circumstances is generally seen most distinctly in the thin lamellar portions of the brain, such as the corpus callosum, the fornix, the Vieussenian valve, the anterior and middle commissures, the septum lucidum. These parts are so soft that unless the greatest care and gentleness are used in the removal of the brain they give way. The softening is not limited to these parts, although greatest in them; it is general throughout the brain. When, however, the hydrocephalic state has been very chronic, the substance of the hemispheres becomes condensed by the pressure from within the ventricles, and the water having thus been pressed out of it, it appears of a natural consistence, or even more dense than natural.

In all the cases of general paralysis of the insane which I have examined, the consistence of the brain generally has been considerably less than natural. There have also been marks of chronic disease of the arachnoid in various patches of opacity, which I am disposed to view rather as a deposit from an abnormal blood than as the result of what is called

* Med. Chir. Trans. vol. xxvii.

chronic inflammation. The softened condition of the brain is doubtless due to a similar cause, the blood yielding vitiated materials for the nutrition of the organ. In brains of this description the dilated and congested state of the veins, and the enlarged and lax condition of the arteries, abundantly demonstrate how sluggish had been the force by which the circulation is maintained in the capillaries, that force of attraction between the blood and the nervous matter, by which more than by any other means active nutrition is maintained.

The parts in which softening when partial is apt to occur in the brain may be thus enumerated according to the order of their frequency —the fornix and septum lucidum, the corpus striatum and optic thalamus, the mesocephale, the corpus callosum and other transverse commissures, the hemispheres of the brain, the cerebellum, the medulla oblongata.

Of the inflammatory or red softening.—Another form of softening of less frequent occurrence than that just described possesses very distinctive characters. It is generally pretty circumscribed in extent, of a diffused redness, most commonly of a bright hue; the consistence of the part is much diminished, and it readily breaks up under the stream of water. Nerve tubes are found in it, more or less varicose and friable, also red particles of the blood, and many of those large nucleated cells commonly known as exudation corpuscles, within which an active molecular motion may be often seen.

The red colour of this form of softening is due partly to the injection of the bloodvessels, and partly to the extravasation of the red particles of the blood throughout the softened part. Sometimes the red colour is absent, although the lesion is essentially the same. In such cases the colour may be yellowish and due to the presence of a less injection of the bloodvessels and a slighter extravasation of the colouring matter of the blood. Dr. Bennet states that he has found exudation corpuscles in a softening of a brilliant white colour, a fact which seems to indicate that the products of inflammation may be present without discoloration, and that all instances of white softening ought not to be considered non-inflammatory.

The researches of Dr. J. H. Bennett, of Edinburgh, are among the most important contributions to the morbid anatomy of the brain of late years. I think he has clearly established that the great characteristic of inflammatory softening is the presence of exudation corpuscles about the minute vessels, and among the elements of the softened cerebral tissue. This is in in the vast majority of instances accompanied with discoloration, which sometimes is due solely to the dark colour of the exudation corpuscles themselves. When these corpuscles are not present, and especially when the softened portion of brain is free from colour, then we must regard the lesion as non-inflammatory, the result of imperfect nutrition, or as produced by physical causes coming into operation shortly before or after death. As the same process of softening which involves the cerebral structure often extends to the minute vessels, small extravasations, constituting the capillary apoplexy of Cruveilhier, frequently occur where no indications of inflammation exist; in such instances the softening, although non-inflammatory, may be of a yellow colour from the effused colouring matter of the blood.

I cannot agree with Dr. Bennett in regarding white softenings as generally *post mortem*, and the result of maceration in serum. The softening of very thin parts, such as the fornix and septum lucidum, no doubt, is frequently of this character. But I have seen many instances of white softening of other parts of the brain which were not exposed to the physical conditions calculated to produce such a change of consistence.

Inflammatory softening occurs most frequently in parts which are near the great vascular surface of the pia mater; the convolutions and the white matter of the centrum ovale, the corpus striatum, and the optic thalamus are the most common situations of this lesion. In thirty-three cases collected by Durand-Fardel the softening was situated in the convolutions in thirty-one, and in nine of them the convolutions were the sole seat of softening. The following table will illustrate the statement above made; it represents the results of fifty-three cases collected from different sources.

Convolutions and white substance	22
Convolutions alone	6
White substance alone	5
Corpus striatum and optic thalamus	6
Corpus striatum alone	11
Optic thalamus alone	4
Pons Varolii	3
Crus cerebri	1
Corpus callosum	1
Walls of the ventricles, septum	1
Fornix	1
Cerebellum	1

Suppuration.—From what has been stated in the previous paragraphs it is plain that the most important sign of inflammation of the brain is red softening. Infiltration of pus is rare. Dr. Bennett states that in no single instance of numerous examinations made by him could softening be traced to the presence or infiltration of pus. This is a direct refutation of Lallemand's assertion that this form of softening owes its colour to the infiltration of pus. Pus, however, is sometimes collected into a cavity in the brain, forming an abscess. An excavation of greater or less size is formed in the substance of the brain, and this is lined by a yellowish membraniform layer, which resembles either lymph in an expanded form, or the purulent matter itself in a less liquid form, compressed into the form of a membrane by the accumulated liquid.

Pus in the brain is of slow formation, and has often become collected in considerable quantity before it betokens its presence by any symptoms. Sometimes we have the opportunity of examining it before it has acquired the yellow colour and oily consistence of laudable pus. In this stage it may be mistaken for some malignant formation; it is whitish, semi-solid, and sometimes mixed with streaks of blood. Its true nature may be recognized by microscopical examination, which discloses the characteristic pus globules with little or no *liquor puris*, and by mixing some of it with liquor potassæ, when it becomes converted into a viscid material resembling white of egg.

Pus in the brain is frequently of a green colour, and very commonly exhales an extremely fetid odour.

The cerebral matter around the purulent collection is either somewhat indurated or it is in an œdematous state, or in one of inflammatory softening. When in this latter state the abscess is not so defined; the softened cerebral matter around it is broken up and mingled with pus; this, however, is rare.

An abscess of the brain may open upon the exterior and so evacuate its contents. This may occur either into the nose through the cribriform plate, or into the tympanic cavity or the external auditory meatus. It is sometimes difficult to determine whether inflammatory disease had arisen in the ear, extending to the brain and exciting the formation of abscess, or whether the abscess already formed in the brain had not burst into the ear. A cerebral abscess may empty itself into either of the ventricles.

Abscesses are most commonly found in one of the cerebral hemispheres, or in the cerebellum; they are very rarely met with in other parts of the brain. Sometimes collections of pus form upon the surface of the brain between the pia mater and the grey matter of the cerebral convolutions. And pus or puriform matter is frequently found between the arachnoid and pia mater, where there has been inflammation of either or of both those membranes. This is most common in children.

Hyperæmia and Anæmia.—An organ so largely supplied with blood as the brain, is liable to variations in the amount of that supply under various circumstances. It is unnecessary to recapitulate here the arguments already adduced to show that the opinions of those who maintain that the quantity of blood in the brain cannot vary, is erroneous. Indeed it is much to be wondered at how persons accustomed to inspect the brain post mortem could have adopted such a doctrine.

In the greatest degree of hyperæmia of the brain, all the vessels of the organ are full; the veins which lie between the convolutions are full; the vessels of the pia mater are fully injected. Often there are diffused extravasations through the areolæ of this membrane, causing a red blotch over more or less of the surface of the brain. The grey matter of the convolutions is extremely dark in colour, and if a small portion of it be examined under the microscope the minute vessels which abound in it are found distended with blood. On the surface of a section of the white matter numerous bloody points are found, being the orifices of vessels cut across. These points are sometimes very large; sometimes they are surrounded by small extravasations of blood, proceeding from the rupture of some small vessel. In this state of the brain the vessels of the choroid plexus and of the velum interpositum are very full, and also those of the dura mater.

Cerebral hyperæmia is generally caused by some obstruction to the free return of the blood to the right side of the heart. Hence we see it always after death by asphyxia, and very commonly in cases of disease of the heart. When the breathing has been seriously impeded just before death, there will always be considerable hyperæmia of the brain. Hence in judging of the nature of a cerebral hyperæmia, the anatomist may be materially assisted in coming to a correct conclusion if he can ascertain the cause of death and the symptoms immediately preceding it; a fact which clearly denotes how little is the value of mere dissection of morbid parts, unassociated with some knowledge of the symptoms manifested during life.

In the bodies of persons dead of epilepsy, during or immediately after the epileptic fit, there is always cerebral hyperæmia. In these cases the hyperæmia is due to the retardation and obstruction of the venous circulation, occasioned by the convulsive struggles of the patient and the resulting impediment to respiration. It may be caused, likewise, by an increased attraction of blood to the organ taking place at the moment of the occurrence of the fit. For the same reason, whenever death is ushered in by convulsions, the brain will be found in a state of congestion, the amount of which will vary with the quantity of blood in the body. Whatever may be the condition of the brain prior to the epileptic paroxysm, it is always in a more or less congested state during and immediately after it. The too prevalent notion that cerebral congestion is the cause of the epileptic paroxysm has but little foundation, while there is abundant evidence to prove that the epileptic paroxysm may give rise to cerebral congestion. It is well known that animals bled to death die in convulsions; and many cases of puerperal convulsions are clearly caused by excessive loss of blood resulting from parturition.

Hyperæmia of the brain is frequently found after death from depressing and exhausting maladies, typhus fever, &c., all diseases of the low typhoid type, and in cases of general paralysis. The powers by which the circulation is carried on in the vessels are greatly depressed, and the blood accumulates in them, especially in the veins.

I know of no means of distinguishing active from passive hyperæmia, excepting probably that the capillaries may be more injected in the former, and the veins more filled in the latter. To enable the anatomist to make a correct distinction, the detail of symptoms during life must be called to his assistance.

Anæmia.—This condition, the opposite to that last considered, is very common. It is frequently met with in children, and in such cases is accompanied with more or less of serous fluid, either in the subarachnoid space or within the ventricles. The brain of the ill-nourished strumous child is generally an anæmic brain.

Anæmia of the brain occurs when death has been caused, whether quickly or gradually, by the loss of blood. It is also present when the heart, oppressed by some disease affecting its own structure, fails to propel the blood with its proper force to the brain. The delirium which comes on in rheumatic fever, when pericarditis or endocarditis commences, is indicative of an anæmic state of the brain; and in some instances in which I have had the opportunity of examining the brain, when the patient died in this delirium, I have found marked and obvious anæmia of this organ.

Anæmia of the brain, according to my observation, is of two kinds, general and partial. In the former, pallor prevails throughout the brain. This is met with, as before mentioned, in ill-nourished children; and it is also present to a remarkable degree in persons, house-painters and others, who have largely imbibed the poison of lead, as if the presence of that poison interfered greatly with the process of hæmatosis. Partial anæmia is where the deficiency of blood is observed chiefly in the grey matter. I have frequently seen the grey matter of the convolutions perfectly bloodless, and the white matter of the hemisphere covered with bloody points of congested veins. This is the condition generally met with after death from rheumatic or gouty delirium.

When the brain is very anæmic a considerable quantity of fluid is generally found beneath the arachnoid membrane, with or without a small quantity in the ventricles; or more rarely, a good deal of fluid in the ventricles, with little or no subarachnoid fluid.

Of cerebral hemorrhage. — Effused blood from one or more ruptured bloodvessels is found upon the surface, in the substance, or in the ventricles of the brain. Effusion of blood in any or all of these situations constitutes the most common form of cerebral apoplexy.

The blood is sometimes effused simply upon the surface of the brain; it is diffused beneath the arachnoid membrane, and even under the pia mater, raising up that membrane and separating it from its connection with the cerebral substance. Not unfrequently such a diffusion of blood beneath the pia mater is connected with an internal extravasation which has made its way to the surface either through broken down cerebral substance or from the ventricles.

A recent apoplexy in the substance of the brain is no more than a dark clot of blood, like a mass of black currant jelly, filling a cavity which it has formed for itself in the cerebral substance. Such is the appearance when the examination has been made a few hours or even a few days after the apoplectic fit. If the patient survive this period, we find evidence of changes in the clot and in the surrounding cerebral substance. These changes vary according to the condition of the brain prior to the apoplectic effusion.

If the brain has been quite healthy up to the occurrence of the rupture, a condition which is extremely rare, then the changes towards cicatrization take place quickly; the serum of the clot becomes absorbed; the torn brain-substance around the clot contracts; the solid matter of the clot assumes a reddish instead of a black hue; it gradually diminishes in quantity, and the brain-substance, not contracting to the same extent as the clot has done, a cavity remains, which contains serum, and more or less of the remnant of the clot. The cerebral substance forming the wall of this cavity has a yellowish colour, somewhat of the same hue as that which is seen after extravasated blood in the subcutaneous tissue, and it is denser than is natural. After the lapse of more time the cavity contracts, and nothing remains but a spot of discoloured and somewhat indurated cerebral substance. When the apoplectic clot has been of large size, and has occasioned an extensive solution of continuity, the contraction of the surrounding substance is not sufficient to obliterate the cavity, which in such instances is occupied by a soft, loose, areolar tissue, infiltrated with fluid. In other cases the cavity is lined by a distinct membrane and is filled with fluid, forming a true cyst. Cruveilhier affirms that the most frequent sequel to the apoplectic clot is the indurated and discoloured spot of cerebral substance; next in frequency is the cavity with the loose areolar tissue; and last, the cavity lined by a membrane or the serous cyst.

The morbid condition which surrounds the apoplectic effusion is generally that of colourless softening. This state doubtless precedes the rupture which gave rise to the hemorrhage. Sometimes, however, red softening extends around it more or less; this generally follows the effusion. The existence of either of these morbid states is very unfavourable to the contraction and cicatrisation of the apoplectic cyst.

It frequently happens that in the cerebral substance around an apoplectic clot we find very numerous small points of effused blood, sometimes accompanied by minute streaks following the direction of the cerebral fibres. This constitutes what is called *capillary apoplexy.* Sometimes this is the only marked appearance present, and no large clot has been formed. This occurs not uncommonly in apoplexy affecting the medulla oblongata and the mesocephale. When many such minute effusions take place very near to each other, it is easy to understand how by their coalition they may form a large apoplectic clot; and it is most probable that large effusions generally arise in this way, not from the rupture of one or even of a few vessels, but from that of numerous minute ones.

The size of the apoplectic clot varies considerably (excluding the cases of capillary apoplexy in which no coalition has taken place) from the size of a millet seed to that of a man's fist, the clot sometimes breaking up the fibrous nervous matter of the hemisphere with its surrounding grey layer, and completely occupying its interior. There is no part of the brain so favourable for the occurrence of a large apoplectic clot as the hemisphere, because its softness and magnitude afford the least resistance to the flux of blood.

Apoplectic effusions occur most frequently in the hemispheres of the brain, affecting first the corpora striata or optic thalami, and spreading from them into the white substance of the hemisphere, or sometimes breaking up their substance and passing into the lateral ventricle of one side, and thence through the foramen of Monro into the lateral ventricle of the other side. The convolutions are the next most frequent seat of apoplexy, and after them either hemisphere of the cerebellum, and either crus cerebri. The pons, crus cerebri, crus cerebelli, are much less frequently affected by hemorrhage. These parts are denser in structure and less freely supplied with blood, and, therefore, less prone to apoplectic effusion than those before mentioned.

Cancer of the brain.—Cancer is occasionally, although very rarely, found affecting some part of the encephalon; most frequently it extends into some portion of it from the meninges.

Andral has given a good history of this diseased condition, founded upon the analysis of forty-three cases.* Of these, the hemispheres were the seat of the cancer in thirty-one, in five the cerebellum was affected, once the mesocephale, three times the pituitary body, and three times the spinal cord.

The number and size of the cancerous tumors are very various. The cancer may begin in the meninges, and attack the bone on the one hand and the brain on the other; or it may be first developed in the substance of the hemispheie. When the disease is superficial the cranial walls may become extensively implicated. I have seen the greater part of the parietal bone implicated in a cancerous tumor. Andral mentions a case in which the frontal and temporal bones were completely destroyed, and another in which the cancer, developed at the inferior surface of the brain, passed out through the foramina of the base of the cranium.

Cerebral cancer is most frequently of the soft or fungoid kind, but sometimes it occurs in the form of small hard tumours, deposited in various parts of the brain, and separated from the surrounding cerebral substance by a distinct membrane or capsule. Frequently it appears to be primary, or at least there seems no evident connection between it and any other cancerous deposit situate elsewhere. Of Andral's forty cases only ten were associated with cancer in other situations.

Tubercle of the brain.—The anatomical characters of tubercle of the brain are very definite. The colour is yellow, the more conspicuous by reason of the white or grey of the surrounding cerebral texture; the consistence cheesy. Its section affords a smooth and clean surface, but if broken up by the point of the knife, its texture appears to be minutely granular. Sometimes this tubercular matter may be picked out of a very distinct capsule. The tubercles vary very much in size, sometimes as small as a millet seed, frequently the size of a split pea, or even as large as a filbert or a walnut, rarely much larger.

The parts of the brain most frequently affected by tubercle are the cerebral hemispheres and those of the cerebellum. The mesocephale and the medulla oblongata are rarely the seat of it. It is generally situated near the surface or near some process of pia mater; consequently it is most commonly met with in the grey matter of the brain.

Cerebral tubercle excites inflammation in the surrounding brain substance, which is then found in the state of red softening; and sometimes suppuration may be established, the tubercular matter being more or less broken down and diffused in the pus. It is thus that tubercles of the brain prove so destructive to life. They may remain quiescent and undetected and even unsuspected until some irritation, often propagated from the periphery, excites surrounding inflammation, which by reason of the presence of the foreign matter of the tubercle, is kept up, and refuses to yield to any measure of treatment. Cerebral tubercle exhibits no spontaneous tendency to soften, nor does it frequently degenerate into earthy concretions.

Entozoa.—The entozoa found in the brain are the *cysticercus cellulosæ*, and the *acephalocyst*, with its denizen the *echinococcus*. Like tubercles, these are always placed near the vascular surface, and they may be said more properly to infest the pia mater than the substance of the brain; by their growth, however, they encroach more or less upon it. The animals sometimes die, and their containing cysts shrink up and become converted into earthy matter, forming calcareous tumors of variable size in the substance or on the surface of the brain.

Morbid states of the ventricles of the brain.—The diseased conditions of the ventricles of the brain are referable, first, to the cavities themselves; secondly, to their contents; thirdly, to their lining membrane and to the choroid plexus.

The most frequent morbid condition of the ventricles is a state of dilatation, which is always passive, being produced by the accumulation of water in it. This retention of fluid within these cavities appears to be a true dropsy, and is in most cases connected with an external meningeal inflammation in a strumous constitution. It is in children that we most frequently meet with this dilatation of the ventricles, and in them it constitutes the disease called *hydrocephalus internus*. In adults it occurs sometimes, but extremely rarely. In the former, when the disease is of a very chronic nature, the fluid will accumulate to a very great extent, and enlarge not only the ventricles but the cranium itself to an enormous size.

In persons in advanced age, in lunatics of long standing, and in old epileptics, we frequently see a dilated state of the ventricles from distension by water. This is always associated with a wasted state of the brain; this fluid, as well as the external fluid, serving to fill up the space from which the cerebral matter had receded.

In all these cases the ventricles which experience dilatation are the lateral ventricles, the third and the fourth. In a very few instances the fifth ventricle has been found similarly dilated.

The fluid contained in the ventricles is generally a clear straw-coloured serum, varying in

* Clin. Med., t. v., p. 633.

quantity from half an ounce to several ounces. Sometimes it is milky, and has shreds of lymph floating in it; at other times it may be sero-purulent, but this is extremely rare, and only occurs when the lining membrane has been the seat of acute inflammation and of inflammatory deposit.

The lining membrane of the ventricles, which in health is of extreme tenuity, becomes frequently thickened and partially opaque in chronic disease of the brain, where the ventricles are more or less dilated. In acute disease lymph is sometimes deposited upon it in large and loose flakes, easily removeable from it. And sometimes there is a deposit all over its surface of a fine granular semitransparent lymph, which gives to the internal surface of the membrane the appearance of an extremely fine and delicate reticulation.

As the choroid plexus are covered by a prolongation of the membrane of the ventricles, their investment is apt to participate in any morbid process which may take place in the former. In acute affections it will be covered with lymph, as the membrane lining the ventricles is elsewhere. When much water has been accumulated in the ventricles, the choroid plexus are pushed against their floor, flattened, and rendered pale by maceration. On the other hand, whatever causes much vascular congestion in the vessels of the brain will produce the same effect in a marked manner upon those of the choroid plexus.

Earthy concretions are sometimes found in the choroid plexus, which may probably be an augmentation of the crystalline matter found in them in their healthy state. These appear to consist chiefly of phosphate and carbonate of lime.

A very common appearance found in the choroid plexus consists in certain vesicles, very variable both in size and number. These are simple cysts, containing a straw-coloured fluid. Formerly they used to be regarded as hydatids, but they are now known to be essentially distinct from them. They occur frequently in brains which exhibit no other departure from the normal condition. Of their precise nature, and of their cause and mode of formation, nothing is known; and as they are seldom of a large size they are not likely so to disturb the functions of the brain as to give rise to symptoms by which their presence could be detected.

On the pseudo-morbid appearances of the nervous centres and their coverings.—The actual indications afforded by any departure from the normal physical condition of the nervous centres after death are so important to the attainment of right conclusions respecting the pathology of the nervous system, that it behoves the anatomist to take fully into account all those circumstances which may give rise to appearances in the cerebro-spinal centres or their membranes simulating disease. Such appearances, not inappropriately termed *pseudo-morbid*, occur in the greater or less vascular fulness of the membranes and of the centres themselves, in the variations in the quantity of fluid around or within the brain, or around the spinal cord, and in the consistence of the nervous matter.

The circumstances which affect the amount of blood in the vessels are the mode of death and the position in which the head has been laid after death. Death by asphyxia, whether rapid or gradual, favours the accumulation of blood in the vessels of the brain. Convulsions preceding death likewise cause turgescence of these vessels. Any impediment to the circulation through the heart has the same effect, but to the greatest degree when the impediment is much felt on the right side of the heart.

The position of the head after death affects the vascular fulness by favouring the accumulation of blood in the most dependent parts. From this circumstance and from the custom of placing bodies on the back, we always find the posterior lobes of the cerebral hemispheres and the cerebellum most filled with blood, and it is on this account that the straight and other posterior sinuses of the dura mater are always filled with blood.

The quantity of fluid around the brain and spinal cord is least in the young and greatest in the old: it is influenced by the bulk of the brain or spinal cord, sometimes disappearing entirely when the brain is so large as to fill the cranial cavity; it is inversely as the quantity of blood, and therefore is considerable in cases of anæmic brain, unless the bulk of the organ have increased from some other cause. Slow deaths from chronic disease favour the accumulation of this fluid by diminishing the supply of blood to the brain. In phthisis and other lingering maladies there is almost always a considerable amount of subarachnoid fluid. The practitioner should bear in mind that the *absence* of subarachnoid fluid is always abnormal, and is in general due to an enlargement of the brain from hyperæmia or from some other cause.

Softening of the nervous matter may be pseudo-morbid. The spinal cord softens very soon after death; but if examined within twenty-four hours it exhibits more density than the brain. With the advance of decomposition the cord becomes extremely soft and almost diffluent. In the brain the pseudo-morbid softening is colourless, and may be readily mistaken for disease. That the brain is very prone to imbibe fluids is shown by Dr. Patterson's experiments. The brains of sheep were allowed to remain for a certain number of hours in a given quantity of water, which was rapidly absorbed. The weight of the brains was increased proportionally to the quantity of water which had been imbibed, and the parts most exposed to the fluid were found in a softened state. In one instance the brain was deprived of its membranes on one side, and six hours after death it was immersed in a mixture composed of equal parts of ox-bile and water. It weighed three ounces, seven drams, and four grains when prepared for experiment. After remaining in the mixture thirty-six hours it weighed eight ounces and one dram.* These

* On the pseudo-morbid appearances of the brain, Ed. Med. and Surg. Journ. for 1842, vol. 57.

experiments show that the brain readily imbibes fluid, and that parts in the vicinity of and bathed in fluid may present a pseudo-morbid softening from such imbibition. The fact, thus ascertained, serves to account for the more frequent occurrence of softening in the fornix and septum lucidum than in other parts of the brain. It is obvious that pseudo-morbid softening of this kind would occur only in parts within the ventricle or in the cerebral substance forming their walls, or on the surface of the brain itself, and that it is less likely to be limited to one side than the morbid softening. Now and then, however, in cases of general anasarca, where the blood is in a very watery condition and much fluid is effused, the brain exhibits a softened state from the imbibition of this fluid.

Abnormal anatomy of nerves.—Certain nerves are sometimes absent, from a defect in the developement of the organ to which they are devoted; as the optic nerve, or the olfactory, when their respective organs are wanting. The non-developement of the eye will also cause a non-developement of the fourth pair and the other orbital nerves which influence the movements of the eyeball.

The morbid states of nerves are few and rare. Inflammation of a nerve rarely occurs idiopathically or primarily. Occurring from whatever cause, it would be distinguished by hyperæmia, enlargement, and by deposit of more or less of lymph or pus. In the acute inflammation the nerve would be softened; but in the chronic it would become indurated. Abscess of a nerve is of very rare occurrence.

Inflammatory affections of nerves occur chiefly in connexion with rheumatic or gouty states of the system. Sciatica is, no doubt, an inflammatory affection of the sciatic nerve of the gouty kind. In lumbago probably the muscular nerves of the lumbar muscles are similarly affected.

Atrophy is a condition into which nerves may fall from disuse or from pressure. In it the nerve-fibres shrink, their central axis wastes, and in extreme cases disappears entirely, the tubular membrane becoming plicated and assuming the characters of fibrous tissue. The nerve experiences a great diminution in size, and the wasting is obvious to the naked eye.

Hypertrophy.—Whether a nerve becomes enlarged when more work is thrown upon it, as a muscle does, is as yet quite uncertain. I am disposed to think that the nerve-fibres may acquire some increase of size; but it seems to me impossible that they should become more numerous. The number of nerve-fibres in individual nerves, as that of muscular fibres in muscles, is probably determined at their primary developement,* and they undergo no change but that of length and thickness subsequently. It would not be difficult, by destroying the office of the vagus nerve on one side, to ascertain whether, after the lapse of some time, the other, upon which its function would devolve, acquired any increase in the size of its nerve-fibres.

* A similar law probably prevails with other tissues, namely, that the number of their proximate elements is determined at primary developement, and that in subsequent growth these elements may increase in bulk but not in number.

Certain gangliform tumours are formed upon nerves, to which the term *neuroma* has been applied. They consist of areolar tissue and of nerve-fibres, and seem to be formed by an increased developement of the areolar tissue between the nerve-fibres. These tumours vary considerably in size and number; sometimes they are not larger than a filbert or a gooseberry sometimes as large as a walnut. In genera they are few and limited to one nerve, and their size is proportionate to that of the nerve with which they are connected. In a few rare cases tumours of this kind have been found in immense numbers scattered over the whole cerebro-spinal system.

(R. B. Todd.)

NERVOUS SYSTEM, Physiology of the.—In inquiring into the physiology of the nervous system, the first step is to determine the vital endowments of nerves and of nervous centres.

When a nerve is laid bare in a living animal, and a mechanical or electrical stimulus is applied to it, we do not find as in muscle that a *visible* change in the nerve takes place; on the contrary, the nerve seems to be uninfluenced by the applied stimulus, and the evidence we have to the contrary is derived from the contraction of certain muscles, if the nerve be muscular, or from indications of pain, if it be a nerve of common sensation.

We infer, then, from the contraction of the muscle in the one case, or from the affection of the mind in the other, that the application of the stimulus has wrought a change in the nerve, which, however, is of such a nature as not to be discerned by any means of observation within our reach. We get, however, excellent proof of the excitation of the change in the nerve, from the fact that when a ligature is applied to a nerve sufficiently tight to produce a solution of continuity in the nerve fibres, the propagation of the influence of the stimulus beyond the ligature is checked. No kind nor degree of stimulation of a muscular nerve above a ligature so applied is capable of exciting muscular contraction.

The most remarkable feature which we notice in the experiment of stimulating a muscular nerve, is *the instantaneousness* with which the muscular contraction takes place. Although the muscles may be at a considerable distance from the point of the nerve to which the stimulus is applied, there seems no appreciable interval of time between the application of the stimulus and the contraction of the muscle. And the cessation of the muscular contraction, instantly upon the removal of the stimulus, is equally conspicuous.

It would appear, then, that the change in the nerve is produced and is propagated along the nerve to distant parts, as it were at one and the same moment. This rapidity of the production, and the instantaneousness of propagation of the change in the nerve, denote that the nerve fibres must be the seat of a molecular change rapidly propagated along the nerve, from molecule to molecule, from the point of application of the stimulus. The change is obviously analogous to that which takes place in the particles of a piece of soft iron, in virtue of which the iron acquires the properties of a magnet, so long as it is maintained in a certain relation to a galvanic current; the magnetic power being instantly communicated when the circuit is completed, and as rapidly removed when it is interrupted.

The action of the stimulus, then, excites a *state of polarity* of the particles of the nerve stimulated; and this polar state may be induced in other particles, whether muscular or nervous, with which the nerve stimulated may be in organic connexion. Just as the polar state of the electrical apparatus is capable of being communicated to the piece of soft iron, which thereby acquires the well-known magnetic properties during the continuance of the excited polarity.

Thus, then, we learn that such is the nature of the nerve fibre, that under the application of a stimulus, mechanical, chemical, or galvanic, it is capable of generating a polar force analogous in many particulars to that of muscle; this force we call the nervous force, *vis nervosa*, or *nervous polarity*.*

And if we examine the ordinary mode of the development of the nervous force, in the usual actions of the frame, we find that under the influence of a mental stimulus, the will, it is propagated from the nervous centre along the nerves to muscles, or under the influence of a physical stimulus it is propagated along the nerves to the centres, where it is capable of exciting either a sensation or muscular motion in a secondary manner, or both.

But the application of a physical stimulus to a nervous centre may cause the development of nervous force, which may be conducted away from it by nerves which are implanted in it. And thus we learn that the same polar condition which may be produced in nerves is equally capable of being excited in nervous centres. The polar condition of the nerve fibre may be propagated to the nervous centre, or that of the nervous centre to the nerve fibre.

In some of the nervous centres, however, no *visible* change of any kind takes place upon the irritation of the nervous matter, nor does the animal seem to suffer pain. Such is the case when the hemispheres of the brain are the subject of experiment. We are not to infer from this that the nervous force is not developed in these centres, but that they have no direct connexion with the muscular system, nor have they that peculiar organization which would enable them when irritated to excite painful sensations.

There are certain nerves which when stimulated excite neither muscular motion nor common sensation or pain, but a sensation peculiar to themselves. Thus if the optic nerve be stimulated by a mechanical or galvanic stimulus, a sensation of light is produced; if the auditory nerve be stimulated in like manner, a sensation of sound is produced.

These facts prove not only that a peculiar force is generated by the nervous matter, but they also show that the nerve fibres in the centres, as well as in the nerves, possess special endowments depending, in all probability, upon their central as well as upon their peripheral connexions. Thus nerve-fibres connected with muscles are capable of exciting muscular contraction, and are therefore called *motor* or *muscular* nerves. Nerve-fibres, which are distributed to a sentient surface, as the skin or mucous membrane, and have a certain relation with that part of the nervous centre which constitutes the centre of sensation, (vide p. 711,) are when stimulated capable of exciting a feeling which may be agreeable or painful, according to the degree of stimulation. These are called *sensitive nerves*, or *nerves of common sensation*. To the class of sensitive nerves belong those which, owing no doubt to a peculiarity in their connexion with the centre, as well as to their relation to a special apparatus at their periphery, develope peculiar sensations, as the nerves of sight, hearing, taste, &c., and they have been distinguished as *nerves of special sensation*.

Very many sentient nerves are implanted in the nervous centre near to certain motor nerves, so that a stimulus applied to the former is capable of reacting upon the latter, and of exciting motion through their connexion with the muscles. Dr. M. Hall, however, ingeniously supposes that this power resides only in a particular class of nerve-fibres (and not in the ordinary sentient nerves through their closeness of relation with the ordinary motor nerves). A nerve of this kind would constitute an arc, consisting of an *incident* and a *reflex* portion, which are united at the nervous centre. The stimulus is conveyed to the centre by the incident portion, and is then reflected into the reflex or motor portion. Such nerves, Dr. Hall designates *excito-motor*. We shall examine further on the grounds of this hypothesis.

It is an important fact, which Sir C. Bell was the first clearly to prove, that nerve-fibres of different endowments may be bound together in one sheath, forming, in anatomical language, one nerve. Thus a nerve may contain sentient and motor fibres, as the median nerve in the arm, or if we admitted Dr. Hall's hypothesis, it might contain sentient, motor, and excito-motor fibres. And most nerves in the different regions of the body are of this description, i. e. *compound* nerves, made up of sentient and motor fibres bound together in the same sheath, in very different proportions. In many of these nerves, as in the spinal nerves, and the fifth pair, the separation of the fibres of motion from those of sensation exists at the implantation in the centre, and there the fibres of each endowment are collected into a separate bundle, which possesses the endowment proper to its constituent fibres. These are the roots of these

* I have been in the habit of taking this view of the nervous force in my lectures for the last four or five years, and of using the term, *nervous polarity*, as expressive of the nature of the nervous force. This term has likewise been adopted by Mr. Bowman and myself in our work on the Physiological Anatomy and Physiology of Man, vol. i. p. 56, and in the chapters on the Nervous System, *passim*.

nerves, of which one has been satisfactorily proved to be sentient, the other motor, the former being generally the larger, and having the peculiar feature of a ganglion being formed upon it.

There is scarcely a nerve in the body, which, in strictness, ought not to be regarded as a compound one; the physiological character of each nerve must depend on the endowment of the majority of its fibres, and the nerve will be called *sensitive* or *motor*, according to the predominance of motor or sensitive fibres in it. For example, the facial nerve, or *portio dura* of the seventh pair, is called *motor*, because it is almost wholly composed of motor fibres; but it contains, besides, in very much smaller number, some sensitive filaments which it derives from anastomoses with neighbouring nerves. The third, fourth, and sixth nerves are of similar constitution to the facial. In the ramifications of the fifth nerve, on the other hand, the filaments of sensation are predominant; those of motion being much fewer, and confined to the ramifications of its inferior maxillary division.

There is no difference between a motor, and a sensitive nerve as regards structure. Ehrenberg, indeed, endeavoured to establish that the varicose character of the fibre belonged to nerves of special sense; but subsequent observation showed this to be incorrect. We can attribute the difference of endowment of the fibres to no other cause, but to the nature of their peripheral and central connections. The same nervous force is propagated by the fibres of each kind, but whether that force is to excite motion or sensation must depend on the connection of the fibres with muscles in the one case, and with the centre of sensation in the other.

The terms *afferent* and *efferent* have been used in expressing the function of different fibres, and they are convenient terms to a certain extent. But the use of them tends to convey erroneous ideas respecting the change which takes place in a nerve when stimulated, as if that change took place only in one direction. It is true that, in a motor nerve, the stimulus ordinarily acts from the centre, and the nervous force is propagated peripherad; and on the other hand, in the sentient nerve, the stimulus is usually applied at the periphery, and the nervous force proceeds centrad. It is the place at which the stimulus is applied which usually determines the *direction* in which the nervous force travels. But there are no good grounds for supposing that the molecular change consequent upon the stimulation of a nerve is limited to that part of the nerve-fibre which is included between the point stimulated, and the centre or the muscles, where the effect of the stimulation appears; on the contrary, it is not improbable that, at whatever point the stimulus be applied, the whole length of the nerve-fibre participates in the change. This is not unlikely in the case of *motor* nerves. For a continued or violent irritation of a motor nerve, in some part of its course, causing spasm or convulsive movement of the muscles it supplies, may be propagated along its whole length to the centre, and may there give rise to irritation of neighbouring fibres, whether motor or sensitive, exciting more convulsion and pain. The phenomena of many cases of epilepsy, in which the fit begins with irritation of a few muscles, may be referred to in illustration of this position.* And it is also very probable as regards *sensitive* nerves. If the ulnar nerve be irritated when it passes behind the internal condyle, a sensation of tingling is excited, which is referred to the sentient surface of the ring and little fingers; and if the irritation is kept up, the skin of those fingers becomes tender to the touch, its sensibility being very much exalted. This fact cannot be explained unless upon the supposition that the molecular change in the nerve-fibres, produced by the irritation, extended to the periphery as well as to the centre, exalting the excitability of their distal extremities.

It is a highly interesting physiological fact, which has an important practical bearing, that at whatever part of their course sentient nerve-fibres be irritated, the same sensation will be produced, whether the seat of the irritation be the centre, the periphery, or the middle of their course, provided only the same fibres are irritated in the same degree. Thus it frequently happens that sensations are referred to the extremities of a nerve when the existing irritation is situated at its point of implantation in the centre. The sensation of tingling or formication, in the hand or foot, arm or leg, is frequently an indication of cerebral or spinal disease; but the practitioner should not forget that precisely the same sensation may be caused by an irritation taking place in the course of the nerve. I have frequent occasion to estimate the importance of this fact in the treatment of cases of Sciatica. This disease generally consists in an irritated state of the nerve in some part of its course by a gouty matter, and it may be treated with the best effects by blisters applied over the nerve. As, however, the morbid impregnation may have taken place at any part of the course of the nerve, it is a very useful practice, when a single application fails, to apply the blisters over different parts in succession, instead of confining the vesication to one region.

This law of action of sensitive nerves gives the clue to the explanation of the extraordinary but well-attested fact, that persons who have suffered amputation will continue to feel a consciousness of the presence of the amputated limb, immediately after, and often for a long time, or even always, after its removal. I have met with two cases, in one of which the arm, in the other the leg, was amputated so long before as forty years; yet each person declared that he had the sensation of his fingers or toes as distinctly as before the operation. And not only does the consciousness above referred to exist, but likewise, when the principal nerve of the limb is irritated, the patient complains of pains or tingling, which he refers to the fingers

* I am aware that these phenomena admit of another explanation, but there is no reason why they might not likewise originate, in many cases, in irritation of a few motor fibres.

or toes.* In such cases the central segments of the amputated nerve-fibres remain; if they retain their healthy condition, they continue to represent in the sensorium the various points on the surface of the amputated limb, and likewise the muscles which they were destined to supply. If, however, the integrity of the nerve-fibres has been impaired in consequence of any morbid action which may have followed the operation, then the sensation exists imperfectly or not at all.

It may be stated in connection with this subject, and in confirmation of the view above taken, that in many cases of complete paralysis of a limb from cerebral disease, the patient, although perfectly clear in his general mental perceptions, is not conscious of the presence of the paralysed member, and really feels as if it did not exist. I have known instances in which this unconsciousness has been so great that the patient has actually mistaken the paralysed part for the limb of some other person coming in contact with him, or for some entirely foreign substance. One man fancied that his paralysed arm was his wife's, and called to her to take it away. In such cases the morbid state of the brain prohibits the developement of that affection of the centre of sensation upon which the feeling of the connection of the limbs depends.†

The same law of action applies to nerves of special, as to those of common sensation. Thus, whilst ordinarily they propagate to the centre impressions made at the periphery, we find nevertheless that irritation of the nervous trunk at any part of its course may give rise to its peculiar sensation; and if the brain be stimulated at the part in which the nerve is implanted, similar sensations may be produced. The phenomena of vision and hearing which are excited in these ways are called "*subjective*;" they are familiarly known to medical men as not unfrequent precursors of more serious symptoms of cerebral disease. Muscæ volitantes, ocular spectra, and tinnitus aurium, are the most common instances of these phenomena. Pressure on the eyeball, a galvanic current passed through it or very near it, rotation of the body, are capable of giving rise to similar phenomena, by exciting the retina or the central connections of the optic nerve, or by disturbing the circulation of the blood in them. A sense of giddiness, similar to that produced by the means last-named, is also a very common symptom of cerebral affection arising from a disturbed circulation, or from the blood being deficient in one or more of its staminal principles, or vitiated by some morbid element.

The stimuli of nerves.—Nervous action is ordinarily provoked by stimuli of two kinds, *mental* and *physical*. Mental stimuli are those resulting from the exercise of the will, or from thought. Physical are due to some external excitant; light, heat, sound, mechanical stimulation, chemical substances, as acids or alkalis, or electricity.

In all voluntary movements an act of the mind is the excitant of the nerve. Sensations are caused generally by the influence of physical agents upon the peripheral extremities of nerves, which communicate with the *sensorium commune*. The change thus produced in the nerve gives rise, through the medium of this communication, to a corresponding affection of the mind. A mental stimulus, however, may affect a nerve of sensation. Such stimulus would originate in that part of the brain which is the seat of the changes connected with the intellectual actions, and affecting the centre of sensation, would excite in certain sentient nerves a change similar to that which a physical stimulus applied to their peripheral extremities is capable of producing. In this way the mind is capable of exciting pain in any part. When the attention has been long directed to any particular situation, whether it has been previously the seat of pain or not, painful sensations may be excited there. Of this we have many instances in practice. In the treatment of cases of hysteria it is of great importance, on this account, to direct the attention of the patient as much as possible away from any local affection.

Motor nerves are never *immediately* excited by a physical stimulus in the ordinary actions of the body. A physical stimulus acts upon a motor nerve always through a sensitive nerve; the actions thus produced are, commonly, called *reflex actions* from the apparent reflexion of the change excited by the afferent or sensitive nerve in the nervous centre into the motor or efferent nerve. This class of actions was first pointed out and described by Prochaska, who viewed them as consisting " in reflexione impressionum sensoriarum in motorias." The contact of a foreign substance, pressure, titillation, are the ordinary physical means by which such actions may be excited. As a good example of this may be quoted the act of deglutition at the isthmus faucium.

Physical stimuli of other kinds, however, may excite motor nerves. The pressure of a morbid growth of any kind may irritate such nerves and create spasm of the muscles they supply. Any virulent fluid applied to a motor nerve will irritate in a similar way—hot water —liquor potassæ—a mineral acid—a solution of strychnine, &c. And for the same reason certain morbid matters in the blood may irritate nerves whether sensitive or motor, causing the so-called neuralgic pain in the one case, and cramp or spasm in the other.

* Müller records several instances in his Physiology, vol. i. p. 746. *(Eng. edition.)*
There is a man now in King's College Hospital who suffered amputation at the upper third of the arm, and whose entire scapula, with the shoulder joint and great part of the clavicle, was removed by Mr. Fergusson within the last two months. This man still feels his fingers.

† Valentin states that persons who are the subjects of congenital imperfections, or absence of the extremities, have nevertheless the internal sensations of such limbs in their perfect state. According to the view above taken this could not be, unless the primitive nervous fibres are present in their full number in the trunks of the nerves destined for the limb. Repertorium fur Anat. und Phys. 1836, p. 330, and note to Baly's translation of Müller's Physiol. vol. i. p. 747.

Effects of the galvanic stimulus.—The most perfect and powerful physical stimulus of motor nerves, and that which most nearly imitates the natural mental stimulus, is the galvanic current. That the nerve should be duly excited by the galvanic current it is necessary that the current should pass *along* its fibres for however short a distance. If it pass *across* the fibre, and *at right angles* to it, it will produce no effect upon the muscles; but if it travel *along* it, even for the twentieth or a smaller portion of an inch, it will effectually excite the nerve and its muscles, just as when the will stimulates it to action.

The influence of the galvanic current upon nerves is so remarkable that it deserves the careful study of physiologists and of practitioners in medicine who often have recourse to the galvanic stimulus with the hope of rousing the dormant energies of nerves. It is to the Italian school of *Physiciens* that we owe the highly interesting series of facts which have been collected upon the influence of the galvanic current upon nerves, to Galvani, Valli, Volta, Marianini, Nobili, and, although last not least, to my distinguished friend, Professor Matteucci, of Pisa, by whose well-devised experiments and researches a flood of light has been thrown upon this hitherto obscure and difficult subject.

I shall content myself here with briefly noticing the points most deserving of attention as bearing upon the laws of action of the nerves.

1. When a galvanic current is passed for however short a distance along a nerve which contains motor fibres, muscular contractions will be excited at the moment of completing as well at that of breaking the circuit, but not while the current is passing. These phenomena take place whatever be the direction in which the current be passed, whether from the nervous centre towards the periphery, (when the current is distinguished as *the direct current,*) or from the periphery towards the centre (when the current is styled *the inverse current*).

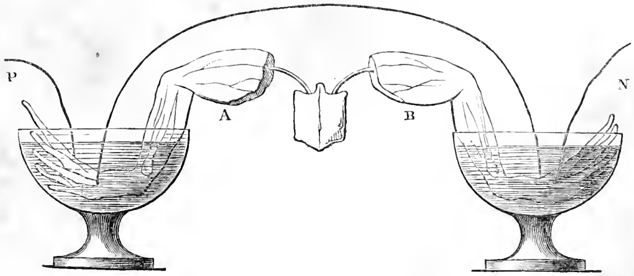
These effects may be produced in warm as well as in cold-blooded animals. In the former, however, the physical conditions necessary for the display of the vital forces continue for so brief a period that cold-blooded animals should be selected for the experiments. On this account, as well as because of their peculiar susceptibility to the galvanic current, frogs are generally employed for this purpose. The most striking way of exhibiting the influence of the current, direct and inverse, upon the nerves is illustrated by the annexed woodcut. It represents a frog prepared in the manner adopted by Galvani. The integuments have been removed from the lower extremities, which have been separated from the trunk by the division of the lumbar region of the spine. The lumbar nerves are carefully raised from the muscles on which they lie, but are suffered to retain their connection with the spinal cord and with the thighs. The pelvic bones, however, are removed so as to admit of the more free separation of the extremities, as well as to isolate the nerves more completely. Each leg is immersed in a glass or cup of water, and the current is made to pass through the limbs by immersing each wire of the battery in the water of the cups. It is obvious that in one limb the current is direct, whilst in the other it is inverse.

The advantage of this arrangement is that it affords great facility in making and breaking the current without bringing the conducting wire of the battery into actual contact with either limb. One wire may be left constantly in the water, while the other can be alternately introduced or removed from it as we wish to observe the effects of completing or of breaking the current.

2. If the current be allowed to pass for a short time through the nerves of a frog, prepared as before-mentioned, contractions will no longer take place in both limbs at the same time, but only in one upon completing the circuit, in the other on breaking. And we shall always find that the contractions occur on making in the limb in which the current is direct, on breaking in the limb in which the current is inverse. I find it useful to adopt the following formula to impress this fact upon the memory; MD, BI, making direct, breaking inverse.

3. If the current continue to pass for some time longer, these phenomena cease completely

Fig. 398*a*.



Lower extremities of the prepared Frog.

P, positive wire of the battery; N, negative ditto. In the limb A the current will be inverse; in B it will be direct.

and no contractions are produced. They may, however, be reproduced by inverting the direction of the current by transposing the conducting wires of the battery. The current will now be inverse in B, and direct in A, *fig.* 398*a*. Or the fact may be illustrated by another disposition of the legs of the frog. Let both feet be immersed in one vessel and the pelvis in the other. The direct current may now be passed along the nerves in both limbs at the same time, until the phenomena of contraction on making or breaking cease. Inverse the current, and the contraction will again become manifest. This fact was first discovered by Volta, and this mode of exhibiting it has been described under the title *Alternatives Voltianes*. If the inverted current continue some time, exhaustion will be produced; but on inverting it again or restoring it to its former course, the actions will recommence.

4. These effects cannot be produced unless the nerves be in a state of integrity. If a ligature be tightly applied to the nerve of either limb close to the muscles, the contractions in that limb will no longer take place. Or to give a more striking illustration of this important fact, if a drop or two of pure sulphuric ether be applied to a point of either nerve, the contractions in the limb of that side will be suspended until the effects of the ether pass off. These experiments unequivocally shew that the nerves are not merely conductors of the electrical current, but that the passage of the current through them developes in them a change which influences the contractile force of the muscles.

5. The influence of the galvanic current affords the most striking results when *motor* nerves are made the subject of the experiments, but Matteucci has shown that sensitive nerves are affected in an analogous way by the inverse and direct current. In a living rabbit the sciatic nerves were exposed, and one nerve was devoted to the direct current, the other to the inverse. Opening and closing both currents were accompanied with marked signs of pain, which, however, were greatest at the closure of the inverse current. After a short time, the signs of pain are manifested only on opening the direct current and closing the inverse.

The reader will scarcely fail to observe that both as regards the sensitive and motor nerves, the effect of the electric current, whether in causing pain or in producing contractions, is greatest when the current passes through the nerve in the course in which the nervous force would naturally proceed in the ordinary nervous actions. It is further worthy of notice that the continuance of the direct current exhausts the power of the nerve, while the reversal of the direction of the current, if not too long delayed, restores it. The continuous passage of the current, however, is not marked either by contractions or by pain. The interruption of the current by any means at once developes these phenomena; or even the diversion of a portion of it produces the same effect, as Marianini showed long ago. If, for instance, the two vessels in which the frog's paws are immersed be connected by a conductor, as an arc of copper or silver wire, contractions will take place on making or breaking the connection; or if the wires of the battery be connected by a third wire of the same material before they dip into the cups, the same effects will be produced.

The continued transmission of an inverse current through a nerve increases to a remarkable extent its excitability. This is shewn by the following experiments: let the limbs of a frog be placed in two vessels of water and the current be passed through them in the manner above described, and let this be continued for a few minutes. After the lapse of this period, if the circuit be broken by taking one of the wires out of the water, the limb in which the current was inverse will be thrown into a state of tonic or tetanoid spasm for a few seconds, the tetanus ceasing with a clonic convulsion on the renewed completion of the circuit.*

That these phenomena are due to a *change developed in the nerve* (not to any affection of the muscles) by the passage of the galvanic current, is clearly demonstrated by applying the galvanic current to a muscle directly, having first removed as much nerve out of it as possible. The muscle will contract equally on making and breaking the circuit, whatever be the direction of the current; nor is it possible to produce tetanic spasm, however long the current may have been continued through it. The following experiment, suggested by Matteucci, also strongly confirms this view. Let the current be passed through the limbs of a frog in the ordinary way. After the current has passed for 25 or 30 minutes, cut the nerve traversed by the inverse current, at the point where it plunges into the thigh, and there will instantly ensue a violent contraction of that limb, which ceases very quickly. If, however, instead of this the nerve be cut where it issues from the spinal cord, *so as to leave a certain* length of the nerve attached to the thigh, there will be a violent contraction of the muscles, which will be followed by others, and the limb will remain in a tetanic state for 10 or 15 seconds or longer.†

The tetanoid contractions of the muscles may be produced by a rapid series of currents passed through the nerve alternately in the inverse and direct course, as by the electro-magnetic or the magneto-electric instrument. These are always greatest and last longest if a portion of the nervous centre remain connected with the limbs. E. H. Weber has lately made a very interesting series of researches by means of the magneto-electric rotation instrument developing the peculiar mode of action of particular muscles.‡

We cannot explain these remarkable phenomena on any other principle than on that which supposes the developement of the nervous force to be associated with the assumption of a polar condition by the molecules of the nerves under the influence of certain stimuli. The inverse current excites a polar state of greater intensity

* Matteucci, Phil. Trans. 1846.
† Comptes Rendus, March 15, 1847.
‡ Wagner, Worterbuch. Art. Muskelbewegung.

and of longer duration than the direct current: hence the tetanic contractions which remain after the interruption of the current.

It is sufficiently obvious why a contraction should occur at the moment of completing the circuit in a nerve. But why the same phenomenon should occur on breaking the circuit is not easily explained. Marianini supposed that during the passage of a direct current through a nerve a part of the electricity accumulated in it, and on the interception of the current discharged itself, traversing the nerve in an opposite direction, and thus giving rise to contractions. It is not, however, likely that such an accumulation would take place, when the conducting power of muscle is so much better than that of nerve. And further, it is evident that this will not explain the absence of contractions in the direct limb after a time on breaking the circuit.

The truth is, that when a continuous current has been passed through the limb of a frog for some time a different state of excitability is established in the nerve of each limb according to the direction which the current had taken. That in which the direct current passes becomes exhausted in its powers, while that in which the inverse current passes has its excitability augmented. In the quiescent state a nerve maintains a certain state of tension: the application of a stimulus modifies this tension and causes the nerve to assume a new polar state, which displays itself in the contraction of muscles or the excitation of a sensation or of pain. The electric current is a powerful stimulus of the nervous force, and the greatest disturbance of the quiescent state of tension is produced by making the direct current. Upon this current beginning to pass, a new state of tension is established, which is disturbed by breaking the circuit: but if the current have continued to pass too long, the maintenance of the state of unnatural tension exhausts the nervous power, and the nerve ceases to respond to any stimulus. Whilst, however, the nerve of the direct limb has assumed one condition, that of the inverse limb has taken on a different one, in which the molecules of the nerve may be conceived to have a disposition the opposite to that which the direct current would produce. Hence only two electric stimuli would restore the particles of the inverse nerve, and so disturb the state of tension into which it had been thrown, namely, making a direct current through the nerve, or simply breaking the inverse.

The tetanoid state which results from the continued passage of the inverse current through a nerve is a phenomenon resulting from the extreme augmentation of its polarity. This state is never produced by the direct current; and the instantaneousness with which it is removed by resuming the current, thereby restoring the state of tension which had been disturbed by breaking the circuit, is highly favourable to this supposition. Anything which weakens the force of the current, or diverts a portion of it from the nerve, as the contact of muscles with the nerve, or of much moisture, or the occasional reversal of the current making it direct where it had been inverse, will materially retard and diminish, or altogether prevent the developement of this phenomenon.

The rapidity with which the changes in the nerves, however they may have been excited, are propagated, and the precision with which they are perceived by the mind in the case of sentient nerves, or produced by it in the case of motor nerves, are well calculated to excite our admiration. If the communication between the nerve and the centre be cut off, the will can exert no influence upon the muscles supplied by the nerve below the section; nor will the mind perceive any stimulus applied to parts which derive their nerves from below the separation. And this for an obvious reason; because the solution of continuity of the nerve interrupts the propagation of the change which the mental or physical stimulus excites in it. In the case of the voluntary nerves, the effects of the mental stimulus are propagated no further *peripherad* than the point of section; and in that of the sensitive nerve, the change travels no further *centrad* than the same point. That this interruption is caused solely by the solution of continuity, and not by any alteration in the properties of the nerve, is proved by the fact that the lower segment of the motor nerve will still continue to respond to a physical stimulus. Mechanical or chemical irritation, or the passage of an electric current along it, will cause its muscles to contract. Such a degree of injury to a nerve as will break the continuity of the nervous matter within the tubular fibres is likewise sufficient to destroy its power as a propagator of nervous change. This effect may be produced by tying a ligature very tightly round a nerve, or by pressing it with great force between the blades of a forceps. The paralysis, which results from the compression of a nerve by a tumour or in any other way, is, no doubt, due to a similar solution of continuity in the nervous matter.

These facts strongly denote the important principle in nervous physiology, that, in propagating the influence of a stimulus, either from periphery to centre, or vice versâ, the whole extent of the nerve-fibre between the point stimulated and its peripheral or central connection is the seat of change; and that the power of developing the nervous force is inherent in the nerve-fibre itself is shown by the fact that the stimulation of a muscular nerve, which has been separated from the centre, below the point of section is capable of exciting muscular action. The conducting power of a nerve, then, results from its proneness to undergo certain changes, physical or chemical, under the influence of stimuli.

We may perceive, then, how important it must be to the healthy action of nerves to preserve them in a sound physical condition. A morbid fluid impregnating a nerve at any point may irritate it, or may suspend or destroy its inherent property by modifying its nutrition or impairing its physical condition. Thus we may paralyse nerves by soaking them in a solution of opium, or of belladonna, aconite, or tobacco, in sulphuric ether, or other sedative or narcotic substances; or, on the other hand, we may unduly excite them by applying a strong solution of strychnia. The contact of a solid body with a nerve may irritate and keep up a continual state of excitement, if it do not destroy its properties. A spiculum of bone, in contact with nervous fibres, is often the cause of the severest forms of neuralgia; inflammation may produce like effects. Various physical agents may produce similar consequences. The benumbing influence of cold is explained in this way. Exposure to a continuous draught of cold air is a frequent cause of facial paralysis. The giving way of a carious tooth will immediately occasion toothache by exposing the nerves of its pulp to the irritating influence of the air, or of the fluids of the mouth. And undue heat is likewise injurious to the physical constitution, and, therefore, to the action of nerves. These facts are of great interest in reference to the pathology of nervous diseases, and suggest that the attraction of a morbid material in the blood to a nerve or set of nerves, or to that part of the nervous centre in which such nerves may be implanted, may afford satisfactory explanation of many obscure phenomena of nerves of sensation.

The organic change, whatever be its intrinsic nature, which stimuli, whether mental or physical, produce in a nerve, developes that wonderful power long known to physiologists by the name *vis nervosa*, the nervous force. This force is more or less engaged in all the functions of the body, whether organic or animal. In the former its office is to regulate, control, and harmonize; in the latter it is the mainspring of action without which none of the phenomena can take place. It is the natural excitant of muscular motion, and the display of that wondrous power depends upon its energy; without vigour in the developement and application of the nervous force, a well-formed muscular system would be of little use, for it would quickly suffer in its nutrition if deprived of that exercise which is essential to it.

In the various combinations of thought which take place in the exercise of the intellect, there can be no doubt that the nervous force is called into play in the hemispheres of the brain. Here the stimulus is mental; the independent operations of the mind excite the action of the appropriate fibres of the brain, and the developement of the nervous force in the brain immediately succeeds the intellectual workings. It is thus that we explain the bodily exhaustion which mental labour induces; and thus, too, we can understand the giving way of the brain—the inducement of cerebral disease—under the incessant wear and tear to which men of great intellectual powers expose it. On the other hand, physical changes in the brain, of a kind different from those which are normal to it, the circulation of too much, or too little, or of a morbid blood, may excite mental phenomena in an irregular way and give rise to delirium or mania.

Of the conditions necessary for the maintenance of the power of developing the nervous force.— From what has been already stated, it is manifest that a healthy physical state of the nervous matter, whether in the nerves or in the nervous centres, constitutes the main condition necessary for preserving in them the power of developing the nervous force. And as nerves will not maintain their healthy nutrition unless they be in union with the nervous centres, this union becomes an important condition for the maintenance of this power in nerves. In the nervous centres the nerves form a connexion with the vesicular matter. We therefore infer that this connexion of the fibrous and vesicular matter is necessary for the exercise of the peculiar power of nerves, because we know of no instance, either in the human economy or in that of the inferior creatures, in which the nervous power is developed without this union.

It is true that if a motor nerve be separated from the nervous centre, its peripheral segment will evince a susceptibility to stimuli, or, in other words, it will retain the power of generating the nervous force for some time after the separation. This is, however, only for a short period, as the experiments of Longet distinctly show. Longet cut out a portion of the sciatic nerve in dogs, and irritated the lower segment of the nerve on each succeeding day by means of galvanism from a pile of twenty couples, and by mechanical irritation. The nerve ceased to be excitable *on and after the fourth day*, ("des le quatrieme jour.")* These results, although they appear to differ from those obtained by Müller and Sticker, and Steinruch, are not really inconsistent with them. These observers, instead of examining and irritating the lower segment of the nerve each succeeding day after the section, allowed it to remain for an arbitrary period untouched, and then reopened the wound to try the effect of stimulating the nerve. Thus Müller and Sticker waited eleven weeks in one rabbit, five weeks in a second, and two months and a half in a dog, and in all the cases found the nerve inexcitable; and Steinruch waited four weeks, at which time he found that the power of the nerve had disappeared. It is obvious that there was nothing in any of these experiments to cast a doubt on the possibility of the nerve having lost its excitability at a much earlier period after the section, and that the selection of five or eight or eleven weeks, as the period when to inquire whether the nerve retained its excitability or not, was entirely arbitrary on the part of the experimenters.

The rapidity with which a nerve loses its power after it has been separated from the nervous centres clearly denotes that connection with the centre is a necessary condition for the nutritive activity of nerves, and is, therefore, a necessary condition for their functional activity, or, in other words, for the full developement of the nervous force under its appropriate stimuli. There are, however, other facts which, inasmuch as they enhance the importance of the vesicular matter in the manifestation of nervous phenomena, give great weight to the proposition under consideration. These are—

* Longet, Recherches Experimentales sur l'Irritabilité Musculaire: l'Examinateur Med. Dec. 1841.

1. That there is invariably an accumulation of vesicular matter around the points of implantation of nerves in the centres, as already referred to. This is true of all nerves in the vertebrata and the higher invertebrata, and we know of no reason to doubt it in the lower invertebrata. 2. The quantity of the vesicular matter around the point of implantation of a nerve is in the direct ratio of its size and of the activity of its function. Under particular circumstances the quantity of vesicular matter becomes so large as to cause a special ganglionic enlargement of the portion of the centre in which the nerve or nerves may be implanted. The cervical and lumbar enlargements of the spinal cord are due to this cause: the gangliform swellings on the upper part of the spinal cord in the gurnard *(trigla lyra)* are connected with the exalted functions of the nerves of touch distributed to the feelers, and contain a large quantity of vesicular matter. A remarkable instance of the developement of vesicular nervous matter under similar circumstances is to be found in the electric lobes of the Torpedo, in which are implanted the nerves distributed to the electrical organ. These lobes are of very considerable size, much exceeding that of any other part of the brain, and they contain vesicular matter in large quantity. The nerves implanted in them are of great size.*

Such facts as those cited in the preceding paragraph denote clearly that the developement of the nervous force is to a certain extent connected with the vesicular nervous matter, and to such a degree as to justify the opinion that this element of the nervous centres may be viewed as the dynamic matter, the originator of the force. At the same time it must be borne in mind that this form of nervous matter never occurs alone, and that probably the union of the two is necessary for the developement of nervous power. Just as the union of two metals in the galvanic battery is necessary for the developement of the current, while one of them, that, namely, which possesses the greatest affinity for the fluid interposed between them, seems to originate the current, and is on that account called the *generating* plate, whilst the other is called the *conducting* plate.

Of the nature of the nervous force.—All that we have said respecting the mode of developement and the laws of the nervous force denotes its polar character.

We can no more detect by our senses any physical change in the piece of soft iron which is rendered *magnetic* by the galvanic current, than we can discover a change in the particles of a nerve stimulated to action by the same current. That both the iron and the nervous matter are thrown into an analogous state by the same agent seems highly probable. In the case of the iron the indication of the assumption and of the maintenance of the polar state is afforded by its power of attracting particles of iron; while in a muscular nerve the assumption and maintenance of the polar state are shown by the active contraction of certain muscles, or a more tonic state of passive contraction. While the current is passing through a motor nerve there is no active contraction of the muscles; but that these organs are in a more excited state than the ordinary one of passive contraction seems evident enough, from the readiness with which they assume a tetanic condition upon the cessation of the passage of an inverse current which had been allowed to pass through their nerves for some time. And the fact demonstrated by Marianini and Matteucci, that the passage of a continuous current through a nerve will after a time exhaust its excitability, although not so quickly as a current frequently interrupted, denotes that the nerve is in an excited state during the actual passage of the galvanic current.

Is the nervous force electricity?—There is so much resemblance, as regards their mode of developement and propagation, between the nervous force and electricity, that many physiologists have been led to regard these forces as identical. The nervous force, however, presents striking points of difference from electricity, which render it highly improbable that it is identical with that force, and which show that if it be so it must be an electricity of extremely low tension.

1. The ordinary tests for electricity fail to detect the existence of a galvanic current in the nerves, whether during their quiescent or their active state. The most delicate galvanometers have been employed for this purpose, in vain, by Prevost and Dumas, who were themselves advocates of the electrical theory of nervous action, by Person, by Müller, by Matteucci, and by myself. Person connected the wires of a galvanometer with the surfaces of the spinal cord in kittens and rabbits, in which spasmodic action of the muscles had been excited by the influence of nux vomica, and was unable to discover any evidence of electrical action. It had been affirmed that needles introduced into the nerves or muscles of living animals became magnetic during nervous and muscular action, so as to attract iron filings, but neither Müller nor Matteucci has succeeded in obtaining such a result from their experiments. Matteucci took the precaution of employing astatic needles for the purpose, but could detect no signs of magnetization. He also introduced the prepared limbs of a frog into the interior of a spiral covered on its inside with varnish; the extremities of this spiral were united to those of another smaller spiral, into which he introduced a wire of soft iron. The nerves of the frog were irritated to excite muscular action, and at the same time Matteucci sought to ascertain if an induced current would traverse the spirals and magnetize the wire, but to no purpose.

2. Were it to be admitted that the nervous force and electricity were identical, it cannot be doubted that the provision made for propagating the latter force in the nerves is very inadequate. The nerves are very imperfect conductors of electricity; Matteucci assigns to them a conducting power four times less than that of muscle; Weber states that they are very

* Savi, Etudes Anat. sur le Système Nerveux et sur l'Organe Electrique de la Torpille.

inferior to the metals as conductors. And from experiments made on this subject in 1845 by Dr. Miller, Mr. Bowman, and myself, we were led to conclude that nerve was infinitely a worse conductor than copper. The provision for insulation, however perfect for the nervous force, seems most insufficient for electricity, unless, perhaps, for a current of very feeble intensity. Yet we know that the nerve fibres convey the mandates of the will with the nicest precision to the muscles, and propagate the effects of physical stimuli applied to the periphery with the greatest exactness to the centre. This could scarcely be if the force so propagated were an imperfectly insulated electric current, for it is evident that in such a bundle of fibres as a nervous trunk disturbances would continually be taking place, from the secondary currents induced in neighbouring fibres by the electricity passing through those in action.

3. The firm application of a ligature to a nerve stops the propagation of the *nervous power* along that nerve below the point of application; the passage of electricity, however, is not interrupted by these means. The nervous trunk, indeed, is as good a conductor of electricity after the application of the ligature as before it, provided it do not become dry at the point of ligature.

4. If a small piece be cut out of the trunk of a nerve, and its place supplied by an electric conductor, electricity will still pass along the nerve and along the conductor; but the nervous force, excited by a stimulus applied above the section, will not be propagated through the conductor to the parts below.

5. The existence of an organ in certain animals capable of generating electricity is unfavourable to the electric nature of the nervous force. The best examples of this organ are found in the Torpedo and the Gymnotus; and experiment has placed it beyond doubt that the organ generates electricity, which is capable of giving a shock similar to that from a Leyden jar; which developes a spark during the discharge, and can effect electrolysis; by which, likewise, the galvanometer may be disturbed, and needles rendered magnetic.*

The electrical organs have no resemblance, in point of structure, to nerves; they, however, present a remarkable analogy in that respect, as well as in their physiological action, to the striped variety of muscles. They are composed of a number of prisms, each of which consists of a membrane closed at both extremities, and containing a soft albuminous substance, but subdivided by transverse very delicate septa into a multitude of small compartments. The bloodvessels and nerves are distributed upon the enclosing membrane and upon the septa, but do not penetrate the albuminous material. On these septa, according to Savi, the nerves form a network, in which the disposition of their terminal fibres differs from that in muscle in there being a true anastomosis or fusion of the primitive tubules. The analogy of the structure of the electrical prisms with that of muscular fibres is sufficiently obvious, the latter being prismatic columns of fibrine, enclosed by a membrane, the sarcolemma, and separable into discs, the nerves and vessels being distributed upon the sarcolemma, and not penetrating the contained sarcous elements. In both these textures the anatomical disposition has evident resemblance to the artificial arrangements for generating electricity, and accordingly in one (the electric organ) true electricity is generated; in the other, as we shall see further on, either electricity, or a force in close relation to electricity, is developed. In both cases the generation of the force is independent of the nervous system; its exercise and application, however, are under the influence of that system.

The arrangement of the nerves and nervous centres is essentially different from that of muscle or of the electric organ, and so far would suggest a decided difference in the character of the force which they can develope from that produced by the latter textures.

6. A comparison of the muscular with the nervous force throws some light on the nature of the latter, and upon its true relation to electricity.

Matteucci has established beyond a shadow of doubt that electricity of feeble tension is generated in the ordinary nutrition of the muscles of all animals, and by a particular arrangement this may be made to assume the current form, passing from the interior to the exterior of the muscle. The source of this electricity is no doubt to be found in the chemical action which accompanies the nutrition of the muscular tissue, "principally that which takes place in the contact of the arterial blood with the muscular fibre."* The intensity of this current increases in proportion to the activity of muscular nutrition, and in proportion to the rank the animals occupy in the scale of beings. It requires a particular artificial arrangement to accumulate the electricity in such a manner as that it shall affect the galvanometer; "during life the two electric states evolved in the muscle neutralize each other at the same points from which they are evolved;" but in the arrangement of a muscular pile as devised by Matteucci, "a portion of this electricity is put in circulation just as it would be in a pile composed of acid and alkali, separated from each other by a simply conducting body."

During the *active contraction* of a muscle, however, a force is developed which has resemblance to electricity, and in his early experiments was regarded in that light by Matteucci. This power is capable of affecting the nerve of the frog in the same manner as electricity. The following experiment displays this:—Take the lower extremity of a frog and skin it; dissect out the sciatic nerve from among the muscles on the posterior part of the thigh, and then separate the thigh by cutting it across just above the knee-joint, leaving the nerve connected with the knee and leg; this preparation is the *galvanoscopic frog*, so called by Matteucci from the readiness with which it indicates an electric current; next prepare the lower extremities of a frog according to Galvani's method:

* See ELECTRICITY, ANIMAL.

* Phil. Trans. 1845, p. 294.

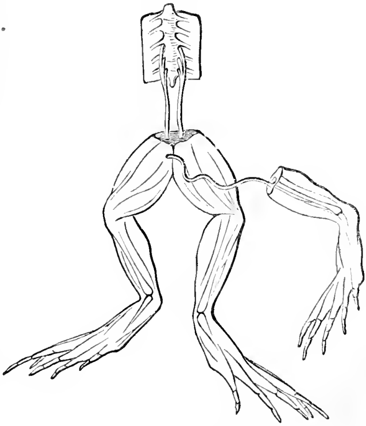
the nerve of the leg is to be laid upon the muscles of either thigh, and if these muscles be excited to contraction by mechanically stimulating the lumbar nerves, or the spinal cord, or by passing a galvanic current through the nerves or the cord, the muscles of the galvanoscopic leg will be simultaneously contracted. If a second and a third galvanoscopic leg be prepared, and the nerve of the second be laid on the muscles of the first, and that of the third be laid upon the muscles of the second, contractions will take place in all three whenever the muscles of the prepared thighs are thrown into contraction. Matteucci, to whom we owe the discovery of this important fact (which he terms *induced contraction**) has failed to cause a fourth leg to be thus affected.

If the galvanoscopic nerve be laid on the muscles of a frog's thigh in which tetanoid convulsions have been produced by the cessation of a long continued inverse current, the induced contractions will be likewise tetanic.†

The annexed woodcuts (*figs.* 398*b* & 398*c*) will serve to show the manner in which these experiments may be performed.

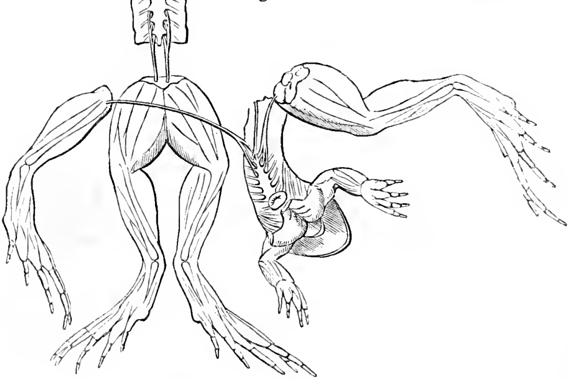
It is plain, then, that during the contraction of muscles, whatever be the means used to stimulate them, a force is evolved capable of exciting a nerve laid upon the exterior of the contracting muscle to such a degree as to cause contraction of the muscles it supplies. What is this force? The readiness with which it excites the nerve of the galvanoscopic leg resembles the action of electricity, and this view of its nature is favoured by the known fact that during muscular contraction heat is evolved, and in some of the marine animals, light also, according to the observations of Quatrefages. If heat and light be produced during muscular contraction, it is not unreasonable to expect that electricity should be evolved likewise. Matteucci's experiments, however, throw some difficulty in the way of viewing it as such. He finds that this force will freely permeate very imperfect conductors of electricity, whilst it will not traverse substances which are known to conduct electricity. If gold leaf be placed upon the muscle between it and the nerve, the con-

Fig. 398*b*.



The limbs of a frog prepared according to Galvani's method, the nerve of the galvanoscopic leg being laid across the muscles of one thigh. When these muscles are thrown into contraction by any means, mechanical or galvanic, those of the leg contract at the same moment.

Fig. 398*c*.



The limbs of a frog prepared after Galvani's fashion. In another frog the galvanoscopic leg is prepared, but the sciatic nerve is left in connection with the lumbar plexus and the spinal cord. If this nerve be laid across the thighs of the frog and the limbs be made to contract, contractions will be simultaneously excited in the galvanoscopic leg and also in the other one. It is plain that while the contractions in the galvanoscopic leg are excited by the direct stimulation of the sciatic nerve, those in the other leg are excited through the excitation of the spinal cord by the sensitive fibres of the same sciatic nerve.

* Phil. Trans. 1845, p. 303.

† Id. 1846, p. 487.

tractions of the galvanoscopic leg will not take place. If, however, a slight tear be made in the gold leaf, then the nerve may be excited. It is possible that this may arise from the electricity being carried off by the gold leaf, so that it does not affect the nerve at all. Matteucci never succeeded in obtaining the induced contractions when a solid body was interposed between the nerve and muscle, however thin it might have been and whatever might be its nature; for this purpose he used flakes of mica extremely thin, flakes of sulphate of lime, gold leaf, paper smeared with glue, and leaves of vegetables.*

On the other hand, in interposing some substances which are known to be bad conductors of electricity, the contractions were obtained. The induced contractions may be excited if the nerve be laid upon the skin over the muscles of the inducing frog. "The experiment," says Matteucci, "never fails of success, whether the inducing contraction be excited by the electric current or by any stimulus applied to the lumbar plexuses of the inducing frog." The use of a very bad conducting body, Venice turpentine, did not prevent the induced contractions. The nearly solid Venice turpentine was rendered more or less liquid by adding to it a little of the volatile oil of turpentine, and with this the muscles were smeared over, and the nerve of the galvanoscopic frog was wetted. To prove the bad conducting powers of the mixture employed, one pole of the exciting pile was applied to the muscle and the other to the galvanoscopic frog without exciting the least contraction. Yet the contractions were induced in the galvanoscopic frog by stimulating the muscles of the thigh. This experiment clearly proved, as Matteucci remarks, that the induced contraction may be excited through a stratum of an insulating substance that prevents the propagation not only of the muscular and proper currents, but also of that current which excites the inducing contraction.

We are forced then by the results of the remarkable experiments above detailed to adopt the conclusion at which Matteucci has himself arrived—that there is no *current* of electricity in the act of muscular contraction. What then is the evolved force? It is either an *electric discharge*† or a force very analogous to electricity, affecting nerves in a similar way, travelling apparently with great rapidity, traversing bodies which the galvanic current cannot traverse, and yet restrained by substances which freely conduct it.

I confess myself at a loss to understand how Matteucci comes to regard this as a phenomenon of the nervous force. In truth, it is a phenomenon which accompanies muscular contraction, and has no relation to the nervous force, excepting so far as that is the excitant of the muscular action. The essential point of the phenomenon is, that during the contraction of a muscle a nerve which is laid on it is stimulated just as it would be by electricity, and causes the muscles to which it is distributed to contract. The electric discharge from a muscle which is excited to contract through the exercise of nervous power is in close analogy with the electric discharge from the electrical organ of the Gymnotus or Torpedo, which is excited through the same agency.

Now the proved existence of a muscular force, the developement of which is accompanied with heat, and most probably electricity, and in some instances, if the statements of Quatrefages be correct, with light, justifies us in adopting the opinion, as regards the nervous force, that this is of an analogous kind, yet exhibiting still less resemblance to electricity than the muscular force; and it strikingly illustrates the remark of Faraday, that if there be reasons for supposing that magnetism is a higher relation of force than electricity, so it may well be imagined that the nervous power may be of a still more exalted character and yet within the reach of experiment.

We are thus led to these conclusions respecting the muscular and nervous forces.

1. That both are polar forces and in close analogy with light, heat, electricity—magnetism.

2. That either may be excited by or transformed into the other—the nervous may excite the muscular, or the muscular the nervous. It seems not improbable that it is by this reaction of the muscular upon the nervous force that the muscular sense is developed, and as Matteucci has ingeniously suggested, many movements independent on the will, yet following others which may be voluntary or otherwise, may result from the same cause.

3. That the same analogy which exists between electricity and magnetism is found between these organic polar forces; the muscular being more nearly allied to the former, the nervous to the latter.

4. Both these forces are dependent on the healthy nutrition of their respective tissues, muscle and nerve, and the slightest disturbance in that process in either tissue will readily affect the intensity of the force.

5. Nevertheless there is a certain mutual dependence between these two tissues and their forces; for the exercise of each is, within certain limits, impossible without the other; and as this exercise is necessary to maintain healthy nutrition, so these forces are to a certain extent dependent on each other for their normal developement. The practitioner in medicine will duly appreciate the great importance of this conclusion.

The mutual reactions of the nervous and muscular forces constitute a new and highly important field of inquiry, which, if duly cultivated, may clear up many obscurities in the physiology and pathology of the nervous system.

Having thus far considered certain generalities in the physiology of the nervous system, we may now proceed to inquire into the share

* Phil. Trans. 1845, On induced contractions.

† From a letter addressed to M. Dumas by Professor Matteucci, and published in the Comptes Rendus for March 15, 1847, it appears that he now is rather disposed to regard it as an electric discharge, as he says, "C'est après avoir prouvé que des décharges electriques de la bouteille tellement faibles qu'elles ne pouvent être montrées par aucun instrument, excepté par la grenouille, que j'ai pensé que la contraction induite pouvait être due à une décharge electrique de ce genre."

which each part of this great system takes in the production of nervous phenomena. This inquiry naturally divides itself into two branches, namely, first, the functions of nerves; secondly, those of nervous centres.

Of the functions of nerves.—Nerves are internuncial; they possess in themselves (separate from the nervous centre) only a very limited power of developing the nervous force, and that only in response to a physical stimulus, for connection with a centre is necessary for the exercise of a mental stimulus.

In inquiring into the function of any particular nerve, the problem is to determine whether it propagates the nervous force *centrad* or *peripherad*, and whether it be connected with the *centre of sensation* or with *the centre of volition;* whether, in short, it be sensitive or motor. It must be always borne in mind that most nerves contain nerve-fibres of different endowments, and that the office of any given nerve will be determined by the endowment of the greatest portion of its fibres. When we say, therefore, that a nerve is motor or sensitive, it is not to be understood that all its fibres are exclusively of that function, and that it contains no others of a different endowment.

In enquiring into the function of a nerve, the first point to determine is its anatomy, whereby we learn whether it be distributed to muscular parts or to sentient surfaces; and then to ascertain whether its distribution in man corresponds with that in the inferior animals. Anatomy, human and comparative, affords by far the most certain grounds to enable us to decide upon the endowment of a nerve: if the nerve be distributed to muscular parts, it is evident that it cannot be a merely sentient nerve, although it may contain some sentient fibres.

Experiment upon animals recently dead also affords considerable aid in reference to questions of this kind. Mechanical or chemical or galvanic irritation of a nerve will cause muscular contractions if it be a motor nerve, and will produce no perceptible change in either nerve or muscles if it be not muscular. Under certain circumstances, however, simple irritation of a nerve, while it evinces no change in the nerve itself or in the parts with which it is connected, will affect the portion of the nervous centre in which it is implanted, and will through that excite certain motor nerves to stimulate their muscles. To affect motor nerves through sensitive ones, it is generally necessary to stimulate their peripheral fibres, the entire trunk remaining uninterrupted in its course; and it would appear as if a certain peripheral organisation, as for instance a developement of papillæ on the tegumentary surface, were necessary for this purpose. Very rarely irritation of *the trunk* of a sentient nerve produces this effect; the least equivocal instance indeed in which, so far as I know, muscular action can be produced in this way, i. e., by irritation of the central segment of the trunk of a nerve, is in the case of the glosso-pharyngeal nerve. Dr. John Reid has succeeded, after section of this nerve, in producing contraction of the pharyngeal muscles by stimulating its central segment.

MM. Longet and Matteucci affirm that a motor nerve may be distinguished from a compound one by the different effect produced on each by opening or closing a galvanic current, according to the direction in which it passes in the nerve. We have referred above to the results of experiments on compound nerves, the sciatic for instance, by means of the electric current. Compound nerves, as has been shown by these means, may at first be affected equally on opening as on closing the circuit, whether the current be direct or inverse; but after a time they are excitable, as shown by the contraction of the muscles below the point stimulated, only on *closing the direct current* or *opening the inverse.* With a purely motor nerve, however, such as the anterior root of a spinal nerve, a different result is obtained after the first period has passed; inasmuch as the contractions of the muscles can only be excited *on opening the direct current or closing the inverse.**

Experiment upon living animals likewise affords us some assistance in determining the functions of nerves. This mode of inquiry, however, must be used with great circumspection, and great caution must be observed in the interpretation of the results which it elicits. Section of a nerve paralyses its function, and occasions loss of motor or of sensitive power, according to the nature of the parts to which the nerve is distributed. Experiment of this kind, however, frequently leads to very unsatisfactory results, because it is often a matter of extreme difficulty to reach the nerve in question; the operation for that purpose may involve other parts and nerves as well, and sometimes it may be impossible to divide one nerve without injuring another immediately adjacent to it. Moreover, the shock of a severe operation frequently produces so much disturbance in the entire system of the animal as to render it extremely difficult to form any accurate opinion as to the effects of the section of the nerve under examination.

Clinical medicine gives very important aid to physiological enquiries of this nature. Disease or injury of certain nerves impairs or destroys or modifies certain functions. The various forms of partial paralysis, especially those affecting the face, may be referred to in illustration of this assertion. Thus a very distinct series of signs accompany disease of the facial nerve or the portio dura of the seventh pair; and these signs mark it very distinctly as

* Matteucci et Longet, sur la relation qui existe entre le sens du courant electrique, et les contractions musculaires dues à ce courant. Paris, 1844.

It is an extraordinary circumstance that the excitability of motor nerve-fibres should be modified by their simple juxtaposition with sensitive fibres.

I learn from a recent communication from Prof. Matteucci, (May, 1847,) that he finds that etherization in dogs modifies the excitability of the nerves, so that the mixed nerves, while connected with the nervous centre, react with the direct or inverse current as the motor nerves do, and excite contractions on opening the direct current or closing the inverse; but the moment their connection with the cord is destroyed they exhibit the phenomena of mixed nerves, causing contraction with the direct current on closing, and with the inverse on opening.

the motor nerve to the muscles of the features, and to the orbicular muscles of the eyelids. Clinical research, indeed, taken in conjunction with anatomy, forms the basis of our present accurate knowledge of the office of this nerve. In like manner we learn that loss of sensibility of the face is dependent on disease affecting the fifth nerve, and from the parts of the face which are affected by anæsthesia we can tell what portions of that great nerve are diseased. Here again anatomy and clinical medicine have mainly contributed to the advance of our knowledge. The partial palsies which affect the muscles of the eye-ball likewise give very distinct interpretation to the functions of these nerves, such as the third and sixth, the action of whose muscles is well understood. Many other instances might be quoted which clearly show that, while clinical medicine and anatomy are of infinite service in building up and confirming our knowledge of the function of nerves, this knowledge, in its turn, does great service in increasing the facility with which we can distinguish disease.

Of the functions of the roots of spinal nerves.—The greatest part of the body is supplied with nerves which are implanted in the spinal cord, or which, in anatomical language, have their origin in that nervous centre. As these nerves present very definite and constant characters as regards the manner in which they are connected with the centre, characters which are not limited to the human subject, but which belong to all classes of vertebrate animals, it was a point of primary importance to discover the object of an arrangement so peculiar as regards its anatomical characters, and so universal. To our countryman, Sir C. Bell, belongs the great merit of having seen the importance of determining this point as a preliminary step in the investigations into the nervous system; and to him must be awarded the credit of having achieved the discovery of the difference in the endowment of the anterior and of the posterior roots of these nerves. He experimented on young rabbits, by removing the posterior wall of the spinal column. "On laying bare the roots of the spinal nerves," says Sir C. Bell, "I found that I could cut across the posterior fasciculus of nerves, which took its origin from the posterior portion of the spinal marrow, without convulsing the muscles of the back; but that, on touching the anterior fasciculus with the point of the knife, the muscles of the back were immediately convulsed." *

Numerous experimenters, subsequent to Bell, obtained precisely similar results. Muller, however, obtained the most decisive evidence of the proper functions of the roots of the nerves, by experimenting on frogs instead of on mammalia; in the former the spinal canal is of great width, especially at its lower part, and the roots of the nerves can be exposed with great facility, whilst in the latter the operation is tedious, painful, and bloody, the spinal canal narrow, and the roots of the nerves small and difficult to get at. Moreover, the excitability of the nerves lasts very much longer in frogs than in mammalia, and on this account the former animals are well adapted for displaying the effects of section of the roots and the influence of mechanical and other stimuli upon them.

In these experiments, (which I have frequently repeated with similar results,) irritation, mechanical or galvanic, of the anterior root of the spinal nerve always provokes muscular contraction. No such effect follows irritation of the posterior root. Section of the anterior root causes paralysis of motion; section of the posterior root, paralysis of sensation. This latter effect is shown by the entire insensibility to pain evinced on pinching a toe, whilst in the limb of which the posterior roots of the nerves remained entire such irritation is evidently felt acutely. If the anterior roots of the nerves which are distributed to the lower extremities be cut on one side, and the posterior roots on the other, voluntary power without sensation will remain in the latter, and sensation without voluntary power in the former.

Valentin, Seubert, Panizza, and Longet have performed similar experiments on mammiferous animals with precisely similar effects.

I have never seen motion produced by irritation of one of the posterior roots of the spinal nerves still in connexion with the cord, excepting when the galvanic stimulus has been applied, and too strong a current has been employed. Valentin states that he has observed motions so produced in rabbits, but not in frogs and tortoises. Dr. Hall has seen them in the turtle and skate. Van Deen speaks of them as constantly occurring. But Müller denies the power of the posterior roots to excite motion, except by "traction on the cord itself." No such effect ever follows any kind of stimulation of the posterior root when it has been separated from the cord.

The conclusion which inevitably follows from these experiments is that the *anterior root of each spinal nerve is motor, and the posterior sensitive.*

Comparative anatomy confirms this conclusion, by showing that a similar arrangement of the roots of spinal nerves prevails among all classes of vertebrate animals, and that if in any particular class either the motor or sensitive power predominate, there is in correspondence with it a marked developement of the anterior or posterior roots. The frequent occurrence, likewise, of paralysis of sensation and motion, as a consequence of disease within the spinal canal, also tends to the same inference.

Kronenberg finds a small nerve of communication between the posterior and the anterior root, which is looked upon by some as being

* Sir C. Bell's first essay on this subject was printed in 1811. In 1822 Majendie published his first essay in the Journal de Physiologie Exp. t. iii; in 1831 Müller's experiments were published in the Annales des Sciences Nat. and in Froriep's Notizen. Mr. Alexander Shaw has published a temperate and judicious vindication of Sir C. Bell's claims in a volume entitled, "Narrative of the Discoveries of Sir C. Bell in the Nervous System." Lond. 1839.

Valentin is so satisfied of Sir C. Bell's claim to the discovery of the distinct endowments of the roots of the spinal nerves, that he designates the law thereby determined by a title not very euphonous to English ears, Lex *Bell*iana.

the means of giving to the anterior root the slight degree of sensitive power which Majendie attributes to it.

From the determination of the office of each root of the spinal nerves we obtain the further important result, that the nerve, which is formed by the junction of these two roots, is sensitive and motor, and that nervous fibres of different endowments may be bound together in the same sheath constituting one nerve, which is compound in its functions. And the anatomical distribution of spinal nerves, both in man and the inferior animals, to the muscles and sensitive surfaces of the trunk and extremities, is entirely confirmatory of the results thus derived from experiment.

By the use of the various means for determining the functions of nerves, above detailed, and aided by the determination of the law discovered and developed by Bell and others, as to the motor nature of the anterior and the sensitive endowment of the posterior roots, and the subsequent binding together of these fibres in one sheath to form a compound nerve, physiologists have made great advances in determining the functions of the various encephalic nerves, and our knowledge on this subject may be said to have approached more to perfection than that of any other physiological questions. The main facts connected with the anatomy and physiology of each of these nerves will be found under the articles headed by their names.

Of the functions of the nervous centres.—In examining into the functions of the various parts of the cerebro-spinal axis I shall adhere to the definitions already adopted in the previous part of this article, and use the term *spinal cord* as denoting the nervous cylinder within the spinal canal, and the *encephalon* as the intra-cranial mass, consisting of *medulla oblongata, mesocephale, cerebellum*, and *cerebrum*.

Of the functions of the spinal cord.—It was long held that the spinal cord was no more than a bundle of nerves proceeding from or to the brain, and emerging at various points of the vertebral canal to be distributed to their destined regions.*

The anatomy of the organ, however, sufficiently exposed the error of this opinion. The existence of a large quantity of vesicular matter in it varying in quantity according to the bulk of its segments showed that it was more than a mere fasciculus of nerves. Although the true office of the spinal cord was known to physiologists long before, to Prochaska for example, Gall appears to have been the first who adduced the best proofs from anatomy to show that the spinal cord was not a mere appendage to the brain, but a special centre in itself. His principal arguments were derived from the want of any constant proportion in bulk between it and the brain, the spinal cord being small with a large brain, as in man, and large with a small brain, as in the inferior mammalia and in other vertebrata, from the fact that it does not taper gradually in proportion as it gives off nerves, but on the contrary is alternately large or small according to the number and volume of the nerves which are given off from its various segments; and, lastly, from the analogy which he indicated between the spinal cord of vertebrata and the ganglionic chain of articulata, the former consisting of a series of ganglia fused together, the latter remaining separate by reason of the peculiar disposition of the bodies of these animals in distinct segments.

The determination of the functions of the nerves which are intimately connected with or implanted in the spinal cord affords some clue to the solution of the problem as to its own office. There can be no doubt that as the nerves of sensation as well as those of motion of the trunk and extremities are all, to say the least, intimately connected with the cord, this organ must be the medium of the reception and propagation of the sentient impressions made upon the one, and of the mental or physical impulses which excite the others.

If, moreover, we look to the results of experiments on the lower animals, or to the effects of injury or disease in the human body, we obtain the following important facts:—1st, that the perfect connexion of this organ, in all its integrity, with the encephalon is the essential condition for the full and complete exercise of the nervous force, whether for sensation or voluntary motion, as far as regards the trunk and extremities; 2nd, that division of the cord, so as completely to separate the lower from the upper segment, causes paralysis both of sensation and voluntary motion in the parts supplied with nerves from the lower segment; 3rd, if the section be made high up in the neck so as to separate the cord from the medulla oblongata, *all* the parts supplied by spinal nerves will be paralysed in the same way; by such an experiment the spinal cord remains entire, but its continuity with the encephalon is interrupted.

In cases of injury to the vertebral column it may be laid down as the rule that the higher the seat of injury the more extensive will be the paralysis. A man who has received extensive injury of the spinal cord high up in the neck is like a living head and a dead trunk, dead to its own sensations, and to all voluntary control over its movements. The same rule prevails with regard to the effects resulting from disease of the vertebræ or from any intra-spinal growth, or from a morbid state of the cord itself, there being only this difference, that where the morbid change is chronic, the paralytic effects are less marked than in injury or acute disease. In all cases the *extent* of the paralysis affords a correct indication of the seat of the solution of continuity.

If the spinal cord be divided partially in the transverse direction, there will be paralysis of parts *on the same side* with the injury. Dr. Yellowly has put on record an experiment of Sir Astley Cooper's, in which he divided the right half of the spinal cord in a dog just above the first vertebra. The effect was paralysis of the motions of the ribs on the right side, and of the right posterior and posterior extremities, with irritation of those of

* That this was Willis's view a perusal of chapters xviii. and xix. of his Cerebri Anatome will shew.

the left side.* A longitudinal section of the cord along the median line in frogs does not cause paralysis; it gives rise, however, to a temporary disturbance of the functions of the cord which soon subsides.†

Continuity of the spinal cord and encephalon is then the condition necessary to establish the control of the former organ over the *voluntary* movements and *sensations* of the trunk. The disunion of the cord or any portion of it from the encephalon dissociates the cord or the separated segment of it from all participation in mental nervous actions. So long as the cord is united with the brain, it takes a certain share in mental nervous actions, in acts of sensation and volition; this, however, it loses when disease or accident separates the one from the other.

It is plain, then, that the spinal cord, although apart from the encephalon it takes no share in sensations and voluntary actions, (for then, indeed, these phenomena cannot take place as far as regards the trunk and extremities,) while united with the encephalon participates fully in sensori-volitional actions, and its integrity is quite necessary to the perfection of those actions.

I repeat that we are not justified in supposing that the mind localises itself exclusively in some or all of the gangliform bodies, the assemblage of which constitutes the encephalon; but this we may assert, with perfect justice, that when the cord has been separated from the encephalon, the mind appears as it were to cling to the latter organ, and to lose all its connection with the former.

Does then the cord, under these circumstances, lose all its power? Does it, when separate from the encephalon, shew no indication of acting as a nervous centre? Undoubtedly it does show abundant indications. A series of actions, which had attracted the notice of several physiologists, are still capable of being developed through the instrumentality of the whole cord or of any portion of it, the nerves of which may remain uninjured both as to their central and peripheral connections.

Phenomena of this nature may be produced in all vertebrate animals. They are, however, especially marked in the cold-blooded classes, in consequence of the more enduring character of the nervous force in those creatures than in the warm-blooded. Hence frogs, salamanders, snakes, turtles, fishes, have been generally selected by physiologists for exhibiting these phenomena. In the young of warm-blooded animals they are more manifest than in adults of the same class.

If a frog be pithed by dividing the line of junction of the medulla oblongata with the spinal cord, the following effects may be observed. After the first disturbance, general convulsions, &c., consequent upon the division of the cord, the animal, if placed on a table, will assume his ordinary position of rest. In some cases, however, frequent combined movements, much resembling acts of volition, will take place for a longer or shorter time after the operation. When all such disturbance has ceased the animal remains perfectly still and as if in repose, nor does it exhibit the slightest appearance or give the least expression of pain or suffering. It is quite unable to produce any spontaneous or voluntary movement of parts supplied with nerves from below the section, that is, of the trunk or extremities. However one may try to frighten it, it remains in the same place and posture. The only appearance of voluntary motion is the winking of the eyelids, which, however, probably is not excited by the will. If, now, a toe be pinched, instantly the limb is drawn up, or the animal seems to push away the irritating agent, and then draws up the leg again into its old position. Sometimes a stimulus of this kind excites both legs, and causes them to be thrown violently backwards. A similar movement almost constantly follows stimulation of the anus. If the skin be pinched at any part, some neighbouring muscle or muscles will be thrown into action. Irritation of the anterior extremities will occasion movements of them; but it is worthy of note that these movements are seldom so energetic as those of the posterior extremities.

We may remark here, that phenomena of this kind are not confined to the trunk and extremities, which are supplied only by spinal nerves. The head and face, with which the encephalon remains in connection, exhibit similar actions. The slightest touch to the margin of either eyelid or to the surface of the conjunctiva causes instantaneous winking; the attempt to depress the lower jaw for the purpose of opening the mouth is resisted; and the act of deglutition is provoked by applying a mechanical stimulus to the back of the throat.*

Actions similar to those which take place in the decapitated frog, occur in the human subject when the spinal cord has been separated from its encephalic connections by disease or accident. In such cases it is found that although the will cannot move the paralysed parts, the lower extremities for instance, movements do occur

* Med. Chir. Trans. vol. i. p. 200.

† See Flourens' Experiments, Syst. Nerveux.

* Sir Gilbert Blane, in his admirable Croonian Lecture on muscular motion, having drawn the distinction between instinctive and voluntary actions, makes the following remarks. "There are facts which show that instinctive actions, even in animals endowed with brain and nerves, do not depend on sensation. I took a live kitten, a few days old, and divided the spinal marrow by cutting it across at the neck. The hind paws being then irritated by pricking them, and by touching them with a hot wire, the muscles belonging to the posterior extremities were thrown into contraction, so as to produce the motion of shrinking from the injury. The same effects were observed in another kitten after the head was entirely separated from the body." And again, "In an acephalous monster, the like phenomena were observable. It moved up its knees, when the soles of its feet were tickled; it performed the act of suction; passed urine and fæces; and swallowed food." * * * "The like takes place with regard to insects; for, after the head of a bee is separated from the body, the hinder part will sting, upon the application of such a stimulus as would excite the same action in the animal in a perfect state."

in them of which the individual is wholly unconscious, and which he is utterly unable to prevent. Sometimes these take place seemingly quite spontaneously; at other times they are excited by the application of a stimulus to some surface supplied by spinal nerves. The movements of this kind, which seem to occur spontaneously, exhibit so close a resemblance to voluntary actions as to render it impossible to distinguish them, did not the consciousness of the patient in some cases assure him of the inactive state of his will in reference to them.

The comparison of the phenomena which occur in pithed or decapitated animals with the actions developed in man under these morbid states, affords most conclusive evidence as to the important question of the connection of these phenomena with the mind. In a pithed or decapitated animal we can only judge of the exercise of volition or the perception of sensitive impressions by external signs. And so far as these go we are justified in maintaining that, while the mental principle is unextinguished, it nevertheless has lost its influence over or connection with that portion of the cerebro-spinal axis which is separated from the encephalon. But in the human subject we have the evidence of the individual himself, who, from his own consciousness, avows the integrity of his will and perception, but admits their dissociation from those parts of the body whose nerves are implanted in the severed portion of the cord.

Let us refer to such a case as has been already quoted. A man has fallen from a height and fractured or displaced one or more of his cervical vertebræ; we find the patient presenting the following phenomena. His trunk and extremities appear as if dead, excepting the movements of the diaphragm, while the head lives. In full possession of his mental faculties and powers, he is, nevertheless, unconscious, save from the exercise of his sight, of any changes which may affect the parts below his head, nor is the utmost effort of his will sufficient to produce a movement of any, even the smallest, of these parts. If the stunning effect of the accident have passed off, tickling the soles of the feet will be found to cause movements, of which, as well as of the application of the stimulus, the patient *is unconscious;* the introduction of a catheter into the urethra, which the patient *does not feel*, excites the penis to erection. The limbs may be irritated in various ways, but without exciting any effect which the patient can perceive, excepting movements, and these he is aware of only from his happening to see them. It is important to notice that, in cases of this kind, movements are difficult of excitation in the upper extremities, while they are aroused with great facility in the lower.

In these cases movements may be excited in both lower extremities by passing a catheter into the bladder. Sometimes internal changes, the precise nature of which we cannot always appreciate, but which are often the result of the irritation of flatus or other matters in the intestinal canal, excite movements in the lower or even in the upper extremities, and the patient is disturbed by cramps and spasmodic movements, more or less violent, at night. It is very remarkable, that while a patient is almost wholly insensible to external stimuli, he feels and even suffers pain from cramps of this kind.

In the hemiplegic paralysis which results from an apoplectic clot, or some other lesion affecting one side of the brain, when the paralysis is complete, the influence of the will over the paralysed side is altogether cut off, sensibility, however, generally remaining. In such cases it is wonderful how easily movements may be excited in the palsied leg—very rarely in the arm—by the application of stimuli to the sole of the foot, or elsewhere with less facility. The patient, who acknowledges his utter inability to move even one of his toes, is astonished at the rapidity and extent to which the whole lower extremity may be moved by touching the sole of the foot, even with a feather. It is proper to add that there is much variety as regards the extent to which these actions take place in hemiplegic cases, owing to causes not yet fully understood; still they do occur in a large proportion of instances, and in the most marked way. Their developement is frequently in the inverse proportion of the withdrawal of the power of the will. When the paralysis to volition is only imperfect, the effect of stimuli in exciting motions is less obvious, because of the restraining power of the will.

The cases of anencephalic fœtuses may be properly referred to as affording instances of similar movements. In these beings we have no movements which can be supposed to originate in any effort of the will, nor is there any proof of the existence of sensibility. Movements, however, of definite kind do occur under the influence of a stimulus applied to the surface.

Actions of the same kind, i. e., provoked by stimuli applied to some surface to which nerves are distributed, will continue to be manifested in animals after decapitation, not only in the trunk and extremities, but also in those segments of the former with which a portion of the spinal cord remains connected. If the body of a snake or an eel be divided into several segments, each one will exhibit movements for some time upon the application of a stimulus. The same thing may be observed in frogs, salamanders, turtles, and other cold-blooded creatures. It may be shown in a remarkable manner in the male frog in the early spring, during the copulating season. At this period an excessive developement of the papillary texture of the integuments covering the thumbs takes place; and this seems to be connected with the tendency which the male frog exhibits during this period of sexual excitement to lay hold on any thing that is brought within the embrace of his anterior extremities and in contact with the enlarged thumbs. If the animal be made to lay hold firmly of any object, two fingers of the observer, for instance, the head and the posterior half of the trunk may be removed, and yet the anterior extremities will maintain their grasp with as much firmness as if the animal were unmutilated. And when the frog is in full vigour, they will continue their hold for as long as a quarter of an hour or twenty minutes after the removal of the head and the posterior segment of the body. But let the portion of the cord which is connected with the anterior extremities be destroyed, and all such power of movement becomes completely annihilated.

In birds and mammalia phenomena of this kind are less conspicuous than in the cold-blooded animals, because in them the nervous power becomes extinct so speedily after any mutilation of the body. The power itself is no doubt more energetic, as the muscular power is, but it is less lasting.

In the articulate classes movements of precisely the same nature may be observed. The common earthworm may be divided into several pieces, and each piece will continue to writhe so long as the irritation produced by the subdivision remains, and after that has ceased, movements may be excited in any segment by stimulating its surface: the same phenomena are observable in leeches and various insects. These actions are exactly analogous to those in the segments of the divided body of a vertebrate animal. Each portion of the articulate creature has in its proper ganglion the analogue of the piece of the spinal cord remaining with the segment of the vertebrate animal. These phenomena of function, conjoined with certain anatomical resemblances, make it quite certain that the abdominal ganglionic chain of the articulata is analogous, not, as formerly supposed, to the sympathetic system, but to the cerebro-spinal centres of Vertebrata. In both the Vertebrata and the Invertebrate Articulata each segment of the body is provided with its proper ganglionic centre, which is to a certain extent independent of the rest. In the latter, the centres of the segments remain distinct, although connected by fibres which pass from one to the other; but in the former they are as it were fused together at their extremities, and from that fusion results the single cylindrical nervous centre which we call *the spinal cord.*

An experiment, to which attention has been directed by Flourens, illustrates very well the difference in the character of the actions of two portions of the spinal cord, according as the brain is connected with or dissociated from it. The spinal cord of an animal is divided about its middle; when the anterior segment (that which still retains its connection with the brain) is irritated, not only are movements of the anterior extremities produced, but the animal evinces unequivocal signs of pain; when, however, the posterior extremity is irritated, the animal seems not only insensible to pain, but unconscious even of the movements that have been excited in the posterior extremities. If a frog be divided in the back into two segments, the anterior portion crawls about, exhibiting all the indications of sensation and volition; the posterior segment remains quite motionless unless some stimulus be applied to it, when movements more or less active may be excited.

Nothing can be more conclusive than such an experiment, in illustration of the fact that connection with the encephalon is necessary to sensation; and that movements, not only without volition, but also without consciousness, may be excited by stimulating the segments separated from it. But there is nothing in this experiment to justify the conclusion that during the entire and unmutilated state of the cerebro-spinal axis the mind has no connection with the spinal cord. The experiment only shows that when a portion of that great centre has been removed, the mind retains its connection with the higher or encephalic portion, deserting that which is merely spinal.

Direct irritation of the spinal cord is capable of exciting these movements as much as when the stimulus is applied to the skin.

All these motions cease when the spinal cord is removed; no movement of any kind, voluntary or involuntary, can then be excited, except by directly stimulating the muscles, or the nerves which supply them, and such movements want the combined and harmonious character which belongs to those which are excited through the nervous centre.

Division of all the roots of the nerves at their emergence from the spinal cord annihilates these movements as completely as the removal of the cord itself. Under such circumstances no motion can be excited by stimulation of the surface of the body, nor by irritating the cord itself; and this fact may be regarded as an unequivocal proof that the nerves, in ordinary actions, are propagators of the change produced by impressions to or from the centres; and that in the physical nervous actions the stimulus acts, not from one nerve to another directly, but through the afferent nerve upon the centre, which in its turn excites the motor nerve.

All these facts in the physiological history of the spinal cord lead unequivocally to the following conclusions respecting its office:— 1. that the spinal cord (that term being used in its simple anatomical sense, *the intra-spinal mass) in union with the brain* is the instrument of sensation and voluntary motion to the trunk and extremities; 2. that the spinal cord may be the medium for the excitation of movements *independently* of volition or sensation in parts supplied by spinal nerves, either by direct irritation of its substance, or by the influence of a stimulus conveyed to it from some surface of the trunk or extremities by its nerves distributed upon that surface.

Of the physical nervous actions of the cord.— We must pause here to make a more extended reference to those actions of the spinal cord which are capable of being excited by peripheral stimulation, and which are independent of mental change. There is no point in the physiology of the nervous system of more interest or importance than this, inasmuch as these actions are not limited to the cord, but take place in other portions of the cerebro-spinal centre, in which nerves are implanted, and even in ganglions from which nerves take their rise.

The existence of a class of actions like these has long been known to physicians and physiologists. By the name of *sympathetic actions* they excited great interest as to the mode of their production. And anatomists explored the frequent and often intricate anastomoses of nerves in their peripheral distribution with the hope of finding in them some clue to the explanation of these phenomena.

To these actions I prefer to apply the name *physical nervous actions* to mark their peculiar characteristic, namely, *independence of the mind*, and to denote that they are the result of a physical change produced by a physical impression, and therefore, in their causation, wholly independent of mental influence. The term *excito-motory* has been applied to them by Dr. Hall. To this term, however, there appear to me to be several serious objections. First, this term implies that the excitation of motion takes place in no other way than by a mechanism similar to that by which these movements are produced. Secondly, it denotes the existence of a peculiar excito-motory power different from the ordinary *vis nervosa*, the agent in all nervous phenomena. As if this force were not capable of being roused into action at one time by a mental stimulus, at another by a physical stimulus, or at a third by a mental and physical stimulus united. Persons get into the habit of using the terms "excito-motory power," "excito-motory phenomena," as if this power, or these phenomena were something quite peculiar, quite *sui generis*, and limited to a special part of the nervous system, losing sight of the real truth that they differ from voluntary actions only in their mode of excitation, that is, by a physical and not by a mental stimulus. Thirdly, it limits the reflecting power of the nervous centres (*i. e.* the propagation of the change induced by the application of a physical stimulus at the periphery) to reflection *from* sensitive to *motor* nerves. Now there are many facts which shew that reflection may take place from a sensitive to another sensitive nerve, and many of the phenomena of sympathy admit of no other explanation excepting on this principle. And I am by no means prepared to affirm that reflection may not take place from motor to sensitive nerves, or even from motor to other motor nerves, under circumstances of an exalted polarity of the nerves and the centres. Fourthly, some of these so-called *excito-motory* phenomena have nothing to do with muscular action. Take, for example, erection of the penis: it has not been shown that muscular fibres take any part in the production of this phenomenon, or that the stimulus which gives rise to it does more than create a change in the vessels of the penis, which seems due to muscular relaxation rather than to muscular contraction. The excitation of a gland to secrete by stimulating some surface connected with it, as the mammary gland by stimulating the nipple, is no doubt a phenomenon of the same kind, but not one in which muscular fibres are excited to contract.

The term "reflex actions," in accordance with Prochaska's view of the reflecting power of the nervous centre, is objectionable inasmuch as it fails to denote fully the physical character of the phenomena; and, moreover, it is applicable only to a class of the actions in question, those, namely, in which the excitation of a motor or sensitive nerve takes place through the primary excitation of another motor or sensitive nerve. Either this term, however, or that which I have proposed, may be used without inconvenience to science because they involve no particular theory, and yet sufficiently express some leading feature of the phenomena, *reflection* at the centre, in the one case—a physical exciting cause of a phenomenon purely physical in the other. It may be objected to the term "physical nervous action" that the actions produced by the mental stimulus are equally physical in their intrinsic nature. When, however, the term is habitually used in contrast with "mental nervous action," all practical difficulty or objection vanishes—both are physical phenomena,—but one is physical in its essence and also in its exciting cause; the other is physical in its essence, but mental in its cause. The term *physical nervous actions* may be regarded as a generic expression for all those nervous phenomena in which the mind takes no necessary share; *reflex actions* being a specific term denoting those physical nervous actions of which reflexion at the centre is a prominent character. In this sense I shall use these terms respectively.

By none were these phenomena more carefully studied than by Whytt and Prochaska. In 1764 Whytt published his "Observations on Nervous Diseases," a work full of the most valuable clinical and practical information. In the first chapter of this book, "on the structure, use, and sympathy of the nerves," he enumerates various instances of sympathetic actions, and discusses the mode of their production. To show that he regarded in this light the actions which we are now considering, I shall quote one which he adduces as an example. He says: "When the hinder toes of a frog are wounded, immediately after cutting off its head, there is either no motion at all excited in the muscles of the legs, or a very inconsiderable one. But if the toes of this animal be pinched, or wounded with a penknife, ten or fifteen minutes after decollation, the muscles not only of the legs and thighs but also of the trunk of the body are, for the most part, strongly convulsed, and the frog sometimes moves from one place to another."*

Whytt's most important work, in which this subject has been most fully discussed, is the essay on the vital and other involuntary motions of animals, published ten years earlier, in 1754. This physiologist was deeply imbued with a righteous dread of materialism, which led him to such extraordinary lengths in spiritualism, that he ascribed every action and movement of the body to "the immediate energy of the mind or sentient principle;" while he completely repudiated all notion of any mechanical disposition in the intimate nature of these phenomena. As an example of his mode of reasoning upon this subject, and as further evidence that he was well acquainted with the class of actions which we now call reflex or physical, the following passage from the eleventh section of this essay may be cited:—

* Whytt's Works, 4to. edit. p. 501.

"The objection against the mind's producing the vital motions, drawn from their being involuntary, must appear extremely weak; since there are a variety of motions equally independent upon our will, which yet are certainly owing to the mind. Thus, as had been already observed, the contraction of the pupil from light, and the motions of the body from tickling, or the apprehension of it, undoubtedly flow from the mind, notwithstanding their being involuntary. The shutting of the eyelids, when a blow is aimed at the eye, is another instance of a motion performed by the mind in spite of the will; for, as the threatened blow does not, by any corporeal contact, affect the orbicular muscle of the palpebræ, its contraction must necessarily be deduced from the mind, moved to perform this action from the apprehension of something ready to hurt the eye: and if there are some who, by an effort of the will, can restrain this motion of their eyelids, yet this does not proceed so much from the mind's making no attempt, in consequence of the apprehended danger, to close the palpebræ, as from the superior eyelid's being kept up by a strong voluntary contraction of its levator muscle. We cannot, by an effort of the will, either command or restrain the erection of the penis; yet it is evidently owing to the mind: for sudden fear, or anything which fixes our attention strongly and all at once, makes this member quickly subside, though it were ever so fully erected. The titillation, therefore, of the *vesiculæ seminales* by the semen, lascivious thoughts, and other causes, only produce the erection of the penis, as they necessarily excite the mind to determine the blood in greater quantity into its cells."

Whytt's view is best explained in the following passage of the same work:—"Upon the whole, there seems to be in man one sentient and intelligent PRINCIPLE, which is equally the source of life, sense, and motion, as of reason; and which, from the law of its union with the body, exerts more or less of its power and influence as the different circumstances of the several organs actuated by it may require. That this principle operates upon the body, by the intervention of something in the brain or nerves, is, I think, likewise probable; though, as to its particular nature, I presume not to allow myself in any uncertain conjectures; but, perhaps, by means of this connecting medium, the various impressions, made on the several parts of the body, either by internal or external causes, are transmitted to and perceived by the mind; in consequence of which it may determine the nervous influence variously into different organs, and so become the cause of all the vital and involuntary motions as well as of the animal and voluntary. It seems to act necessarily and as a sentient principle only, when its power is excited in causing the former; but in producing the latter it acts freely, and both as a sentient and rational agent."*

* Op. cit., 8vo ed., p. 290.

The third fasciculus of the Annotationes Academicæ of Geo. Prochaska was published in 1784. It contains the Essay on the Functions of the Nervous System. It is impossible to speak too highly of this profound and accurate dissertation. Although short, it comprehends all the leading facts connected with the working of the nervous system, and affords abundant indications that its author had thought deeply on the subject. I know of no essay, of more modern date, which exhibits the same profound knowledge of nervous phenomena, and which is equally comprehensive. How it came to be so long neglected can only be explained by the too general incompetency of physiologists to appreciate his views. Yet his language is remarkably clear and precise. No one can have done more ample justice to his predecessors and contemporaries. His literary research was extensive and accurate, and his historical summary is most interesting and instructive. The attentive perusal of this essay more frequently than once has impressed me strongly with the conviction that Prochaska was a man of the highest mental capacity and of great power of generalization, and I shall rejoice to see his work made easily accessible to all medical readers.

A brief summary of this important work will not be out of place here.

In the first chapter, the first seven sections are occupied with an historical account of the views of preceding philosophers, beginning with Aristotle and Galen. In the eighth section, he remarks, "At length we abandon the Cartesian method of philosophizing in this part of animal physics, and embrace the Newtonian, being persuaded that the slow, nay, the most uncertain road to truth is that by hypothesis and conjecture, but that by far the more certain, more excellent, and the shorter way is that, quæ a posteriori ad causam ducit. Newton distinguished the inscrutable cause of the physical attractions by the name 'force of attraction;' he observed its effects, arranged them, and detected the laws of motion, and thus established a useful doctrine, honourable to human genius. In this way we ought to proceed in the study of the nervous system; the cause latent in the nervous pulp, which produces certain effects, and which hitherto has not been determined, we shall call *vis nervosa;* its observed effects, which are the functions of the nervous system, we shall arrange, and expose their laws, and in this manner we shall be able to construct a true and useful doctrine, quæ arti medicæ novam lucem et faciem elegantiorem datura est pro certo." Haller, he admits, had previously used the term "vis nervosa" to express the power by which nerves cause muscles to contract, but to Unzer he assigns the credit of having thrown the greatest light upon this subject, although he states that to accommodate himself to the times in which he wrote and to make himself more generally understood, he still used the term "animal spirits," although his doctrine was quite independent of such an hypothesis.

In the second chapter Prochaska gives an admirable summary of the leading anatomical characters of the nervous system. His succinct description of the nervous centres is excellent, and shows that he had anticipated views which long afterwards were put forward as original. Speaking of the crura cerebri, he describes them thus, "duo magna crura cerebri, in quibus omnis medulla ab utroque cerebri hemisphærio collecta videtur." The compound origin of the fifth and spinal nerves and the existence of the ganglion on one of their roots he was well acquainted with. He concludes thus, "However complex be the mechanism of the nervous system, I think it can be divided into three parts, just as the functions themselves are conveniently divisible into three classes: namely, first, the animal organs, or those associated with the faculty of thinking, these are the brain and cerebellum; secondly, the *sensorium commune*, which consists of the medulla spinalis and oblongata, not excepting also such part of the medulla of the brain as gives immediate origin to nerves; and, thirdly, the nerves properly so called, which are prolonged from the sensorium commune to the whole body."

An examination of the comparative anatomy of the nervous system next follows, affording a clear and concise exposition of the existing state of knowledge on that subject.

The question discussed in the succeeding section is, "quid per vim nervosam intelligitur, et quæ sint generales ejus proprietates?" and he affirms the principle of the inherence of the vis nervosa in the nervous structure itself, and the developement of that force by changes taking place in it. Leaving it to those who devote themselves to the study of experimental physics to inquire into the nature of the nervous force, he endeavours to determine its general properties or laws before inquiring into the special functions of the nervous system.

1. The first law which he lays down is that the vis nervosa requires, for its action, a stimulus. Here, likewise, he repeats the assertion, that the *vis nervosa* is an innate property of the nervous medulla—"innata pulpæ medullaris proprietas. Sicut scintilla latet in chalybe ac silice, nec prius elicitur, nisi attritus mutuus chalybis, silicisque accesserit: ita vis nervosa latet, nec actiones systematis nervosi prius producit donec stimulo applicito excitatur, quo durante durat, ablato cessat agere, et redeunte iterum reddit."

2. The stimulus necessary for the developement of the nervous force is twofold, *stimulus corporis* and *stimulus animæ*. The former is any body fluid or solid applied externally or internally to the nervous system. The latter is that of the mind, which, through its connection with a part of the nervous system, is capable of influencing, to a certain extent, the rest of that system and through it the body.

3. The vigour of the nervous actions bears a direct relation to that of the nervous force and to the power of the exciting stimulus. The actions of the nervous system will be greater and more vigorous in proportion as the vis nervosa may be more active (mobilior) and the stimulus more efficacious; on the other hand, the nervous force will be more sluggish and the stimulus less effective, where the nervous actions are more languid. A less stimulus is sufficient for a more active vis nervosa, as the application of a stronger stimulus may compensate for a more sluggish vis nervosa, yet an equal effect may be produced in the nervous actions. The nervous force, however, is not equally susceptible to every kind of stimulus; sometimes it obeys one more than another, although both may appear equally powerful: nay, sometimes it experiences a more powerful effect from the stimulus which may seem the mildest. According to Haller, the heart and intestines are more powerfully stimulated to contract by air blown into them than by water or by any poison; on the contrary, a drop of water let fall into the trachea excites violent cough, whereas air passes through it in breathing as if unfelt by it.

4. The nervous force is augmented by various circumstances. Among these he enumerates *age*—at an early age the vis nervosa being greater than at a more advanced period of life—*climate*, and *disease*.

5. On the other hand, the vis nervosa may be depressed or diminished by all causes which depress the powers of life, by the direct application of opium and other sedatives to the nervous matter.

6. "Vis nervosa est divisibilis et absque cerebro in nervis subsistit." In illustration of this law he adduces the instances of nerves remaining excitable after they have been separated from the cord or from the brain; also the excitability of paralytic limbs by the electrical stimulus. And, he states, the vis nervosa not only remains for a long time in the spinal cord and nerves which have been separated from the brain, but even in nerves which never had any connection with the brain, as is shown by the acephalous fœtus, which, without a brain, and by the sole force of the nerves and medulla spinalis, if this be not deficient, lives the full time in the uterus of the mother, is nourished, grows, and, when it comes into the light, shows often no obscure signs of life. To this law he attributes the persistence of the rhythmical action of the heart after the decapitation of animals.

7. Idiosyncrasy is a peculiar affection of the nervous force. Among the examples of idiosyncrasy he enumerates, fainting at the sight of blood, the uneasiness and even terror produced in some persons by the exhalations from a cat, which may be in the same room, although unseen; fainting from the perception of particular odours.

In his third chapter Prochaska proceeds to examine the functions of nerves. He describes the mode of action of nerves, their power of receiving impressions with great facility, and of propagating them with the greatest velocity either to the centre or to the periphery. This power he calls the vis nervosa of nerves, which also may be called the sensibility or mobility of nerves, and to which Unzer had given the name *corporeal sense without concomitant perception*. And he shows that this power is inherent in the medullary pulp of the nerves, and is not simply derived from the brain, but that a certain cohesion of the medullary pulp of the nerves is necessary for the developement of the vis nervosa, because if by compressing a nerve strongly we injure its medulla, so as to disturb the connection of its particles, the nervous force ceases in that part of the compressed nerve, nor are impressions propagated further by it, nor if that part of the nerve be stimulated can sensation or motion be produced.

Although, he says, a nerve is necessary for sense and motion, it is not it alone which feels or moves; it feels by the brain, which, when an impression made upon a nerve is conveyed to it, represents that impression to the mind; and a nerve causes motion by the muscle when an impression, communicated to the nerve, descends to the muscle and excites it to motion. He concludes thus: "Par itaque nervi, in sensu et motu ciendo, est officium, nimirum impressionem stimuli recipere, et per totam suam longitudinem celerrimé propagare, quæ dum ad cerebrum pervenit, sensus perceptionem causat, dum vero ad musculum, ejus contractionem ciet."

Prochaska recognises the influence of the nerves upon the bloodvessels, and ascribes various familiar phenomena to this influence, either excited by direct contact of the nerves of the part, or, if the nerves be indirectly affected through the brain (si isti nervi non immediate, sed mediante cerebro afficiantur). Thus he refers to redness of the skin of the face occasioned by exposure to a cold wind, redness of the conjunctiva caused by some irritant, erection of the nipple of the breast by titillation, erection of the penis by similar means or through mental emotion, blushing, &c. He puts forward the notion that the augmentation of the nervous force in any part causes an attraction of fluids to that part, as sealing-wax, when rubbed with cloth, becomes electrical and attracts various small particles. To a similar attraction of fluids he ascribes muscular action and many other phenomena, such as the menstrual flux, the action of the iris, &c. He also discusses the question whether the nerves have any power over the secretions, whether they contribute in any way to the production of animal heat, and how far they are necessary to nutrition.

The fourth chapter describes *the sensorium commune*, its functions, and its seat. Here it is that Prochaska has put forward his views respecting reflex actions. External impressions, which are made upon sensitive nerves, are propagated with great velocity throughout their entire length to their origin, where, (to use his own phrase,) when they have arrived, they are reflected according to a certain law, and pass into certain and responding (certos ac respondentes) motor nerves, by which again being very quickly propagated to muscles they excite certain and determinate movements. This place, he says, in which, as in a centre, nerves of sense and of motion meet and communicate, and in which "the impressions of sensitive nerves are reflected into motor nerves," is called, by a term already received by most physiologists, "*the sensorium commune*." Having referred to the various views of different physiologists as to the seat of the sensorium commune, he expresses his own opinion, that the sensorium commune, properly so called, extends throughout the medulla oblongata, the crura cerebri and cerebelli, a part of the optic thalami, and the entire spinal cord,—in a word, as far as the origins of the nerves extend. That the sensorium commune extends to the spinal cord is shown by those movements which continue in animals after decapitation, which cannot be effected without the cooperation of nerves which arise from the spinal cord; for if a decapitated frog be pricked, not only does it retract the stimulated part, but also it creeps, and leaps, which could not be done without the consentaneous action (absque consensu) of sensitive and motor nerves, the seat of which consentaneous action must be in the medulla spinalis, *superstite sensorii communis parte*.

That Prochaska viewed these acts as purely physical in their nature, is apparent from his statement, that they take place under peculiar laws, *written, as it were, by nature on the medullary pulp of the sensorium.* The general law, however, whereby the sensorium commune reflects sensorial into motor impressions (impressiones sensorias in motorias reflectit) is our preservation; so that certain motor impressions should succeed to such external impressions as might be injurious to our bodies. In illustration he refers to certain acts of this class, such as, irritation of the mucous membrane of the nose creating a violent act of expiration (sneezing) to expel the offending material from the nostril; the spasmodic closure of the glottis when a particle of food or a drop of fluid touches it, or the act of winking excited by the finger being brought close to the eye.

Prochaska points out that these reflex actions may take place with or without consciousness (vel animâ insciâ, vel vero animâ consciâ). In proof of this occurrence without consciousness he refers to certain acts which are observed in apoplectic patients, to the convulsions of epilepsy, and to certain actions in profound sleep; all those actions which occur in decapitated animals he refers to this class, and regards them as being regulated by the remaining portion of the sensorium commune which is seated in the spinal cord. "Omnes istæ actiones ex organismo et *physicis* legibus, sensorio communi propriis, fluunt, suntque, propterea, spontaneæ ac automaticæ." Actions, however, which the mind directs and moderates by its control, although the *sensorium commune* may take its share in producing them, may be called *animal*, and not automatic.

The second paragraph of this chapter contains an excellent discussion of the question, how far the anastomoses of nerves contribute to their mutual action upon each other, or whether that takes place only through the sensorium commune. On this subject Prochaska adopts the opinions of Whytt, who regarded the nervous centre as essential to these actions, and in the next paragraph he enquires whether nerves can establish any communication or consent with each other in their ganglia, and also discusses the use of ganglia, giving his assent, in some degree, to the doctrine which he assigns to Unzer and Winterl,* that external impressions are capable of being reflected by ganglia as they are reflected in the sensorium commune, and that ganglia are particular centres of sensorial impressions (sensoria particularia). He supposes that the action of the heart may be explained in this way through the impressions made by the blood upon its sensitive nerves which are reflected at the ganglia ;† and he concludes by admitting it to be probable that besides the sensorium commune which resides in the medulla oblongata, the medulla spinalis, &c., there are *sensoria particularia* in ganglia and anastomoses of nerves (concatenationibus nervorum) in which external impressions are reflected, without their reaching the sensorium commune. ‡

In the fifth and last chapter Prochaska discusses the animal functions of the nervous system. He shows that the soul, *ens incorporeæ prosapiæ*, uses the nervous system as an instrument, and that, in all animal functions, it is the *principium agens et determinans*. He describes the principal parts into which the animal functions can be conveniently resolved, as perception, judgment, will, to which may be added imagination and memory. For the exercise of these he lays down that the joint and harmonious action of the mind and brain is necessary, and he assigns to each of them a different locality in the brain. In the last section he again defines the animal actions, and distinguishes them from those which are dependent on a physical exciting cause; and argues against the Stahlian doctrine, which placed each movement and function of the body under the control of the soul.

These doctrines are repeated and somewhat enlarged upon in a much later work by Prochaska, published at Vienna in 1810, entitled, "Lehrsätze aus der Physiologie des Menschen," a third and much enlarged edition of a text book for his lectures. The whole section on the nervous system will repay an attentive perusal, and especially the chapter headed "Verrichtung des allgemeinen Sensoriums," which contains a review of the doctrine of reflex actions. A later edition of the same work, somewhat compressed in some parts, published in 1820, contains a repetition and a distinct enunciation of the same doctrines (p. 92).*

It is not a little remarkable, and at the same time highly discreditable to physiologists, that views so comprehensive and so striking should have been suffered to fall into neglect and to become almost wholly forgotten, and that the peculiar power of nervous centres to develope motions in response to sensorial impressions, or, in Prochaska's language, "to reflect sensorial into motor impressions," should have been lost sight of. Le Gallois, indeed, had recognized this power, and Blane had evidently much insight into it; Mayo, likewise, had formed a very correct appreciation of it, as shown by his observations on the actions of the iris. But none of these physiologists were fully impressed with its immense importance. It is to Dr. Marshall Hall in this country and to Professor Müller in Germany that science is most indebted for awakening the attention of physi-

* Unzer, Gundriss eines Lehrgebaudes von der Sinnlichkeit der thierischen Korper, 1768; also, Ertse Grunde einer Physiologie der eigentlichen thierischen Natur thierischer Korper. 1771. Winterl, Inflammationis nova theoria, Viennæ, 1767. I have not had an opportunity of perusing any of the works of Unzer. They are, indeed, little known in this country, having first appeared at a time when German literature was scarcely at all cultivated here. The only English medical writer with whom I am acquainted, who has made distinct reference to Unzer from having apparently studied his works, is Sir Alexander Crichton, who seems to have formed a high estimate of Unzer's Erste Grunde einer Physiol. as I gather from his work on Mental Derangement, published in 1798. Dr. Baly, the learned translator of Muller's Physiology, also refers to Unzer; and I must express my obligations to an interesting article in Dr. Forbes's journal (the British and Foreign Medical Review) for July, 1847, which contains a good abstract of Unzer's views, with an account of his writings. From this it is plain that Unzer had very enlarged views with reference to the phenomena of the nervous system, and perfectly appreciated the distinction to be made between those actions with which the mind is concerned either as excitor or recipient, and those which in their causation and developement are wholly independent of the mind, although not unperceived by it. The publication of Unzer's principal works and also of Prochaska's in an English dress would be a great boon to the student of the physiology of the nervous system, and would most legitimately come within the scope of the Sydenham Society.

† This is the doctrine in most favour at the present day.

‡ It is plain from the context that Prochaska had no idea of these *sensoria* having any connection with the mind, or with the mental power of perception.

* Geo. Prochaska was born in 1749, and studied medicine at Vienna, where he was clinical assistant to the celebrated De Haen. He published an inaugural dissertation *de urinis*, but the works which first attracted notice were his Quæstiones Physiologicæ, Vienna, 1778; and his treatises De Carne Musculari, and De Structura Nervorum. In 1778 he was made professor of anatomy and of ophthalmic surgery at the University of Prague, where he formed a valuable cabinet of preparations of morbid parts. In 1791 he was translated to a similar chair in the University of Vienna, with the title of Lehrer der höhern Anatomie, Physiologie, und Augenarzneykunde. M. Dezeimeris, from whose Dictionnaire Historique de la Médecine (art. Prochaska) this account is abridged, remarks of him that "he was one of those who strove to reduce the laws of life to the general laws of nature, and to make physiology a branch of experimental physics." Prochaska died on the 17th of July, 1820. The works in which he propounded his views respecting the nervous system are, 1. Annotation. Academic. fasc. iii., Prague, 1784. 2. Lehrsätze aus der Physiol. des Menschen, 1st ed., 1797, in 2 vol.; 2nd ed. 1802; 3rd ed. 1810. 3. Opera minora Physiologici et Pathologici Argumenti, p. i. et ii. 4. Physiologie oder Lehre von der Natur des Menschen, 1820. To these, perhaps, may be added a Latin edition of his Physiology, Institutiones Physiologiæ Humanæ, 1805-6; and Disq. Anatom. Phys. Organismi Corporis Humani, ejusq. Processus Vitalis, 1812; but neither of these works have I seen.

ologists to the existence of a power in the nervous centres which no doubt exercises a wide influence on the phenomena of living creatures; and yet it seems extraordinary that neither of these physiologists in their earlier writings should have made the slightest allusion to Prochaska, who had offered a more precise and more comprehensive, and, as I hope to show, a truer explanation of the phenomena than either of them.

I shall here cite various facts, in addition to those already adduced, which unequivocally demonstrate that a power exists in the cord of exciting movements in parts which receive nerves from it, by changes occurring in its substance, which may arise there from some modification of its nutrition developed in the cord itself, or be excited by a stimulus brought to act upon it by afferent or sensitive nerves.

But more than this: the cord has the power of reflecting the change wrought in it by impressions conducted to it into adjacent sensitive nerves, thus creating a large class of reflex phenomena under the name of reflex or radiating sensations.

When a stimulus is applied to the spinal cord, either directly or through the medium of afferent nerves, the actions excited by it are generally limited to those parts which derive their nerves from that segment of the cord which has received the stimulus. In some instances, however, parts supplied from other and even distant segments are thrown into action. Thus irritation of one leg may cause movements of one or both of the upper extremities; the introduction of a catheter into the urethra will sometimes give rise to forcible contractions of the muscles of the lower extremities or even of all the limbs. These effects are due, no doubt, to the extension of the stimulation in the cord beyond the point first acted upon; and they may be regarded as proofs that that peculiar state of physical change which nervous stimulation can excite in a centre may be propagated in the spinal cord upwards, downwards, or sideways, from the seat of the primary stimulation.

This fact was pointed out first, so far as I know, by Dr. M. Hall, who regards it as a property of the cord in its normal state. This, I am inclined to think, is an error; I believe it to be a property of the cord, only when its polarity is exalted. It is, however, an important property, and we shall, by-and-bye, make use of it in considering the mechanism of the various actions of nervous centres. Meantime we may obtain, from examining into the morbid states which are apt to arise in the spinal cord and in other parts of the cerebro-spinal centres, interesting confirmation of it.

A wound in the sole of the foot or ball of the thumb, or in some other situation favourable to the maintenance of prolonged irritation, is capable of exciting a particular region of the cord, from which the state of excitement spreads so as to involve not only the whole cord, but part of the medulla oblongata also; and in this state a large proportion of the motor nerves participate, so as to induce tonic contraction of the muscles they supply. This is the rationale of the developement of that fearful malady called *tetanus*. It consists not in an inflammatory condition of the cord or of its membranes, nor in congestion of them, but simply in a state of prolonged physical excitement, the natural polar force of the centre being greatly exalted and kept so by the constant irritation propagated to it by the nerves of the wounded part. Intestinal irritation is capable of producing a similar condition, which, if the irritation have not been allowed to remain too long, may be speedily removed by getting rid of the irritating cause. The following case illustrates this: an unhealthy looking girl, about fifteen years of age, was brought into King's College Hospital suffering from severe tonic spasms of the muscles of the spine and lower extremities. The spasms were so powerful as to produce successive paroxysms of opisthotonos, during which the trunk became bent like a bow, so that the patient rested on her occiput and on her heels. This state was speedily removed by the use of a large purgative clyster containing turpentine, which brought away a large number of ascarides from the rectum.

In cases of paraplegia from disease of the spinal cord, the paralysed parts are frequently troubled with cramps and startings occurring chiefly at night, and preventing sleep and occasioning great distress to the patient. These are very often traceable to intestinal disturbance, the presence of irritating matters, which, stimulating the mucous membrane, through its nerves excite the spinal cord, and thus produce these involuntary movements.

The rigid and contracted state of the muscles of paralysed limbs, which frequently accompanies red softening of the brain, arises from the propagation of the excited state of the diseased part of the brain to that portion of the spinal cord which is connected with it, and from which the nerves of the paralysed parts arise. These nerves likewise participate in the irritation of the cord, and thus keep the muscles in a state of continued active contraction. There is no organic lesion of the cord in these cases; its state of excitement is dependent on the cerebral irritation, and disappears if the latter yields to the influence of remedial measures.

To a similar extension of cerebral irritation, although of a much briefer duration, the convulsions of epilepsy may be attributed. The brain becomes the seat of irritation, and this spreads to the whole or a part of the spinal cord and to the nerves which arise from it. In many instances of epilepsy the convulsions are limited to one half of the body, and this is especially the case where a chronic lesion exists in the brain and forms a focus of irritation, which is propagated only to one half (the opposite) of the cord.

Some substances exert a peculiar influence upon the spinal cord and throw it into a state of considerable polar excitement. Strychnine is the most energetic substance of this class. If a certain quantity of this drug be injected into the blood or taken into the stomach of an animal, a state of general tetanus will quickly ensue, sensibility being either unaltered or somewhat exalted. The slightest touch upon the surface of the body, even a breath of wind blown upon it, will cause a general or partial convulsive movement. The whole extent of the spinal cord is in a state of excitement, and even the medulla oblongata may be involved in it, whence the closed jaws, the spasmodic state of the facial muscles, the difficult deglutition. When this polar excitement is raised to its highest degree, the slightest mechanical stimulus applied to any one point of the cord affects the whole organ and throws all the muscles which it supplies into spasmodic contraction, just as the least stimulus to peripheral parts has the same effect.

It is a very interesting fact, which I have frequently satisfied myself of by careful examination, that, however great the polar excitement may have been into which the cord has been thrown by strychnine, it exhibits no change of structure which can be detected by our means of observation. The nerve tubes and other elements entering into the formation of the cord have preserved their natural appearance in all the cases which I have examined.

Opium has the effect of creating a similar state of polarity in the cord. This is most conspicuous in cold-blooded animals; it produces a similar effect in the warm-blooded classes, but in a much less degree. Hence there is an objection to the use of opium in large doses in cases of tetanus; and experience has shewn the inefficacy and the injurious influence of this drug when administered in large quantities. When the cord is in this state of excitement, a stimulus applied to one part may excite a remote part of it with great facility.

The curious tendency already referred to, which the male frog has to grasp objects presented to them by his anterior extremities, is to be attributed in part to a spontaneous exaltation of the polar force of the cord which takes place at the copulating season, in the spring of the year, and which is associated with an extraordinary developement of the papillary texture of the integument of the thumb.

This exaltation of the polar force of the cord, in connection with the generative function, is a point highly worthy of the attention of the physiologist as offering some explanation of the sympathy which exists between different organs, between those even which are remote from each other, during the rutting season, or during utero-gestation.

It is worthy of notice here that cold has a considerable influence in controlling this polar state of the spinal cord, and of other nervous centres likewise. Ice applied along the spine, or the cold douche, may be frequently employed with great benefit in cases of muscular disturbance dependent on this polar state of the cord. It seems to me more than doubtful that many of those drugs which have the character of possessing a sedative influence upon the nervous system can be employed for this purpose either with safety or advantage. This applies certainly to hydrocyanic acid and to opium in large doses; animals poisoned by these substances become convulsed before death, and this denotes their tendency to exalt the polarity of the cord. Conium and belladonna, according to my experience, exercise the most beneficial influence of any of the sedative drugs, and I have found them very useful in restraining the cramps and startings in paraplegic cases.

I have ascertained by several experiments that the inhalation of ether has considerable effect in controlling the natural polar state of the cord, as well as that which may be produced by strychnine. A pigeon deprived of its cerebral hemispheres lives in a state of sleep for a considerable time; it flies when thrown in the air, spreading and flapping its wings; stands when placed on its feet. A bird thus mutilated was made to inhale ether; it could not stand, and when thrown into the air it fell to the ground like a heavy log, its wings remaining applied to the sides of its body, or if the wings were drawn out as it was thrown into the air, they quickly collapsed. As soon as the effects of the ether had passed off, it stood and flew as before. I gave strychnine to a rabbit, a guinea-pig, and a dog, so as to excite the tetanoid state. Immediately the spasms showed themselves, I brought it under the influence of ether; the spasms ceased immediately, and the animal became perfectly relaxed; but as soon as the effects of the ether passed off, the spasms came on again, but were soon subdued by a fresh inhalation of ether. And thus I found that the life of an animal poisoned by strychnine could be greatly prolonged through successive inhalations of ether; for animals of the same kind, poisoned by equal doses of strychnine, but not subjected to the influence of ether, perished very rapidly.

The examples which show that the spinal cord possesses the power of reflecting sensitive impressions are chiefly derived from disease. Every practitioner is familiar with the pain in the knee which accompanies the early stages of disease of the hip joint. The patient sometimes refers his sufferings so exclusively to the former joint, that the disease of the latter may be entirely overlooked by his medical attendant. Yet the really painful part is healthy, while the hip joint is the seat of a morbid process. The pains which are felt in the thighs from the presence of a stone in the bladder, and the itching which is referred to the extremity of the prepuce from the same cause, are phenomena of the same nature. Pain in the right shoulder from irritation of the liver is a well-known sympathetic sensation: sometimes this pain extends over a very large surface.

Numerous other instances of similar sympathetic phenomena might be adduced, but the above are sufficient for our present purpose. Taking into account the well-proved fact that nerves form no real junction of their fibres in their anastomoses, and that there is no more than a simple juxta-position of the nerve-tubes in these anastomoses, it is plain that we must trace these fibres up to the nervous centres to discover any connection between the fibre first irritated and that to which pain is referred. In the case of hip-joint disease, the nerves of the hip are those primarily irritated: there is no connection at the periphery between these nerves and those of the knee; both, however, are of spinal origin, and must be implanted near to each other in the spinal cord. This, then, is the only situation at which any communication may be established between them, and it is probable that that communication takes place through the vesicular matter in which both are implanted. The irritation from the hip, then, extends to the cord; it is there propagated to the vesicular matter in which the nerves of the knee are implanted: in other words, it is reflected to them, and thus pain is referred to the peripheral extremity of those nerves, in conformity with the known law of sensitive nerves, and in this way the pain is felt in the knee. A similar explanation applies to the other cases referred to.

There is no other mode of explaining these phenomena consistently with the known disposition and properties of nerve-fibres; and as experiment demonstrates the reflecting power of the cord from sensitive to motor, we are justified in referring these phenomena to a similar reflecting power from sensitive to sensitive nerves. We shall see further on that other nervous centres possess the same power.

The functions of the body with which the spinal cord is immediately concerned are the following:—1. The voluntary movements and sensations of the trunk and extremities, and of the viscera contained in the thorax, abdomen, and pelvis. For these, however, the integrity of its connection with the brain is necessary. 2. The physical actions, or, in other words, the involuntary movements of the trunk and extremities. 3. The actions necessary for locomotion, which are a combination of mental and physical nervous actions. 4. The physical actions of some of the internal organs. These are the heart, the intestinal canal, the bladder, and the generative organs, both male and female. The influence of the spinal cord over all these organs is, however, very limited, and inasmuch as they have a considerable degree of inherent muscular power, as well as receive nerves connected with other centres, namely, the sympathetic ganglia, they are in a great degree independent of the cord.

Dr. M. Hall's doctrines.—Using the term spinal cord to designate a centre or axis of physical nervous actions *(the true spinal cord)*, provoked by "excitor" nerves of the head, neck, trunk, and extremities, and of parts connected with them, Dr. Marshall Hall assigns to it very extended functions.

"Every act of ingestion, of retention, of expulsion, or of exclusion," says this physiologist,* "is a reflex act; an excito-motor act, an act of the true spinal system, performed through its incident nerves, its central organ (the true spinal marrow), and its reflex motor nerves; an act of the special power seated in this system." * * * * * "If we wish, then, to know what are the special acts of the true spinal system, we have only to ask what are the acts by means of which masses of matter are ingurgitated into and expelled from the animal economy." And in a table which follows these paragraphs, and which is intended to display at one view the physiology of the true spinal system (so called), he refers to this source, I. The excited actions: 1, of the iris and eyelids; 2, of the orifices—the larynx and the pharynx; 3, of the ingestion (1, of the food, as in suction and in deglutition; 2, of the air in respiration; 3, of the semen or conception); 4, of exclusion; 5, of the expulsion or of egestion (1, of the fæces; 2, of the urine; 3, of the perspiration; 4, of the semen; 5, of the fœtus or parturition); 6, of the sphincters (1, of the cardia; 2, the valvula Coli? (sic); 3, the sphincter ani; 4, the sphincter vesicæ). II. The direct action or influence: 1, in the tone; and 2, in the irritability of the muscular system.*

I shall content myself here with pointing out how slight are the grounds upon which so large a function is assigned to the spinal system, and so exclusive a view is taken of the various actions which are affirmed to be under its control. Further on I hope to show that the hypothesis of a special centre (the true spinal narrow) with its incident and reflex nerves is inadequate to the explanation of the phenomena of the nervous system.

A careful analysis of the various acts of ingestion, &c. will show that they cannot be regarded entirely as reflex acts. Thus the ingestion of food is effected by prehension, which is voluntary, by suction, as in the young, which is partly voluntary and partly reflex, and by deglutition. Now this last act is partly voluntary, as in the mouth; when the food has been brought within the grasp of the fauces it is reflex, and that portion of the act which takes place in the œsophagus is partly reflex and partly due to the influence of the stimulus of distension upon the muscular coat. The most purely physical portion of the act of deglutition is that which takes place in the vicinity of the rima glottidis, which, if not regulated by very exact physical changes, and if not, in a great degree at least, independent of mind, might frequently endanger the life of the individual by the deviation of the morsel of food from its proper course, so as to plug up or encroach upon the orifice which leads to the respiratory organs.†

The act of respiration is undoubtedly essentially reflex, but it is likewise very much under the control of the will, and may at any time be increased or diminished in frequency under the influence of either volition or emotion.

In conception, or what Dr. Hall calls the ingestion of semen, I am at a loss to conceive what reflex act can occur. The grasping of the ovary by the extremity of the Fallopian tube is more likely to be an act of emotion due to the general sexual excitement than a reflex phenomenon excited by the stimulus of coition. And as to the ingestion of the seminal fluid, that

* New Memoir on the Nervous System, 1843, p. 51, § 191-192.

* Loc. cit. p. 52.

† Here we notice the operation of the law of our preservation, which, according to Prochaska, regulates these reflex acts.

is wholly independent of the nervous system, and is effected partly by the forcible injection of the fluid into the vagina and uterus, and partly by the ciliary movement of the spermatic particles, the so-called spermatozoa.

The acts of retention cannot certainly be regarded as wholly reflex. Taking the instances quoted by Dr. Marshall Hall, the action of the sphincters, we shall find but little evidence in support of his view. The sphincter ani, the most perfect and complete of the sphincters, is *a voluntary muscle*, endowed with a high degree of contractile power; its circular form renders it very prone to act under the stimulus of distension, and it therefore resists any distending force, whether from above or below. This resistance, however, is powerfully increased by voluntary effort, as on the other hand it is materially diminished if the muscle be separated from cerebral influence. The habitual closed state of the anus, during the quiescence of the rectum, is effected by the tone or passive contraction, which requires for its perfect developement only that the muscle should enjoy a healthy nutrition. As long as this remains, the sphincter closes the orifice of the rectum sufficiently to prevent the escape of a small quantity of matter from it; this power, however, does not enable it to resist any considerable pressure; such resistance can only be effected by the active contraction of the muscle, effected partly by the stimulus of distension, and partly and chiefly by volition.

The voluntary nature of the actions of the sphincter is obvious from the personal feelings of each individual. It is also sufficiently indicated by the fact that if the spinal cord be divided in any region by disease or injury, so as to induce complete paralysis of the lower extremities without muscular rigidity, the sphincter will be paralysed, however extensive the inferior segment of the cord may be. Were its actions entirely or even chiefly of the reflex kind, the continuance of the lower segment of the cord in the healthy state ought to preserve their integrity. But this is never the case excepting in the rare instance of a persistent state of irritation of the inferior segment of the cord sufficient to maintain rigidity of the muscles of the lower limbs, and also to provoke a continued state of active contraction. It is, however, possible that a physical stimulus applied to the mucous membrane of the rectum or anus may excite by reflex action the contraction of the sphincter, and thus come in aid of voluntary power, and of the inherent contractility of the muscle; but such aid is called forth only under peculiar circumstances, and either not at all or to a very trifling extent in the ordinary action of the sphincter. Moreover, in deep-seated and extensive lesion of the brain, paralysis of the sphincter ani is a constant symptom, the spinal cord being perfectly healthy, and the reflex actions of the paralysed lower extremity (for in such cases the paralysis is generally hemiplegic) well marked. Such cases must be regarded as affording the most conclusive evidence against the reflex nature of the action of the sphincter ani, and all the facts that I have mentioned denote abundantly that the reflex action of the sphincter ani is the exception and not the rule.

The experiments which Dr. Hall adduces in support of the reflex nature of the action of the sphincter are inconclusive for this purpose. They consisted in the division of the spinal cord in a horse and a turtle, and the excitation of reflex actions *immediately* afterwards. If the experiment be repeated in a dog, the following result will be observed: immediately after the division of the cord the sphincter will contract repeatedly without the application of any new stimulus, and the dog will raise and depress his tail, and these phenomena will continue as long as the irritation produced in the cord by the section remains. When this irritated condition shall have passed off, the experimenter will find it impossible to excite the action of the sphincter muscle by stimulating the anus. If the actions of this muscle were of the reflex kind, surely they ought to continue as long as the segment of the cord with which its nerves are connected shall retain its powers intact.

A remarkable degree of sensibility exists in the cutaneous covering of the verge of the anus in most animals, which is calculated to mislead with reference to the reflex nature of the action of the sphincter. In the decapitated frog, stimulation of the anus excites forcible extension of the posterior extremities. Mr. Grainger describes a phenomenon which was noticed by Professor Bischoff in the green frog (*Rana arborea*), so common in many parts of Germany. "Upon irritating the cloaca in one of these animals which had been decapitated, the most violent emotions were excited in the hind legs, and *repeated attempts were made by these limbs to remove the instrument* with which the cloaca was touched. This fact," adds Mr. Grainger, "I have since repeatedly seen in the green and common frog, both when the head was removed and when the spinal cord was divided in the back."* I can add my testimony to this fact, having witnessed it many times in the common frog.

Dr. Hall himself, indeed, furnishes experimental evidence well calculated to cast a doubt upon his views of the nature of the action of the sphincter, and to indicate the existence of some source of fallacy in his experiments. The subject of experiment was a turtle; in one experiment, it is stated, "the sphincter was perfectly circular and closed; it was contracted still more forcibly on the application of a stimulus."† In a second experiment, he says, "if, when the cloaca is distended, the integuments over it are stimulated, the water is propelled to a considerable distance."‡ Here are two opposing actions caused by stimulation of the same region of the integument!

With regard to the sphincter vesicæ, or more properly to the circular fibres of the muscular coat of the bladder, the influence of the will cannot be denied. Voluntary influence through the vesical nerves and the irritability of the

* Grainger on the Spinal Cord, p. 59.
† First Mem. § 37.
‡ Second Mem. § 172.

muscular coat of the bladder are the usual means by which the action of this viscus is promoted. It is possible that, as with the rectum, under peculiar circumstances the physical stimulus acting reflexly on the muscular fibres themselves may come in aid of that of volition; but such a mode of action is not the ordinary one. A line of argument similar to that which disproves the reflex nature of the action of the sphincter ani tells equally against that of the sphincter vesicæ. Were the action of this muscle reflex, it ought to remain perfect whenever a sufficiently large segment of the cord remains in connexion with the bladder. Now when the spinal cord is severed in any region so as to occasion paralysis of the lower extremities, there is almost always incontinence of urine from the removal of voluntary influence from the sphincter vesicæ: such ought not to be the case, if Dr. Hall's views were correct.

Respecting the cardia and the valvula coli, I shall only remark that the evidence of reflex action is extremely defective. The cardia, indeed, has no sphincter; it is closed by the lower circular fibres of the œsophagus, which keep that canal in a contracted state by their tone or passive contraction. The pylorus is provided with a sphincter muscle of great power, which closes that orifice by its passive contraction, and which in animals recently killed will continue to close the orifice as long as the muscle retains its tone. If an animal be killed during stomach digestion, the stomach may be removed, and yet the pylorus will retain the food in it even against gravity; the cardia, if a sufficient portion of the œsophagus be retained, will resist the escape of the food; but, from the absence of a true sphincter, to a much less degree than the pylorus. It is impossible that, under these circumstances, there could be any reflex action, as the stomach is removed from its connection with the nervous centre. The valvula coli appears to act simply on mechanical principles.

There is, I apprehend, no more evidence of the exclusively reflex nature of the acts of expulsion than of that of the acts of retention. The expulsion of the fæces and that of the urine are voluntary acts, aided essentially by the contractile power of the muscular fibres of each viscus, and perhaps, under peculiar circumstances, by a physical excitant. Were this power reflex, the expulsion would be no doubt much more frequent and much less under control, and, therefore, productive of frequent serious inconvenience. The expulsion of perspiration is probably effected by the simplest mechanical means, the newly secreted fluid pushing before it that which was previously formed. The expulsion of the semen does, indeed, exhibit the characters of a true reflex act; but here how marked is the physical stimulus, and how necessary that it should reach a certain point of excitement before the action of expulsion responds to it! As to the expulsion of the fœtus in parturition, while I am willing to admit that the physical power of the cord excited by the sensitive nerves at the neck of the uterus may exercise some influence on the contractions of the uterus, it seems to me quite evident that the actions of this organ are reflex only to a very slight degree. In the first place, anatomy teaches us that the muscular parts of the uterus have a very trifling connexion with the spinal cord; the nerves distributed to it being few, and these only partially derived from the spinal cord. Secondly, parturition may take place even when the spinal cord has been diseased or divided so as to cut off its influence upon the inferior half of the body. Thirdly, it has lately been ascertained that in women under the influence of ether, the act of parturition may take place with vigour, although the nervous power have been very considerably depressed by the influence of that agent.

The immediate agent of expulsion in defæcation, micturition, and parturition is the inherent contractility of the muscular coat of the proper organ. Being hollow muscles, the stimulus of distension is well adapted to excite them to contract. The will exercises considerable power in defæcation and micturition, both upon the muscular fibres of the viscera themselves, and on the abdominal muscles. In parturition the voluntary contraction of these latter muscles may give some assistance, but the main force of expulsion is due to the contraction of the uterine muscular fibres. In all the three actions, however, the influence of the muscular fibres of the viscera respectively engaged may be materially promoted by the contractions of the abdominal muscles, which are partly voluntary and partly reflex, being excited by the pressure of the mass to be expelled on the sensitive nerves in the neighbourhood, which, acting on the spinal cord, stimulate the muscular nerves, and through them cause the muscles they supply to contract, in harmony with the muscular tunic of the expelling viscus, rectum, bladder, or uterus, as the case may be.

I may here remark, that whilst it is sufficiently evident that expulsion of the semen is a physical or reflex act, it cannot be admitted that erection of the penis is essentially so in its ordinary mode of production. This act is one of emotion—a simple emotion of the mind is sufficient to develope it: it may, however, be developed by the application of a stimulus to the penis or scrotum, when it clearly partakes of the character of a reflex act, although even under these circumstances it would be incorrect to say that emotion had no influence in its production. It is well known, however, that in cases where the spinal cord has been severely injured, severed indeed, by fracture and displacement of some of the vertebræ, erection of the penis may be produced, although the organ is insensible, and the influence of the mind over the lower half of the body is suspended, and that even a slight stimulus, as the friction of the bedclothes, or the introduction of a catheter, is sufficient for this purpose. This is clearly a purely reflex act, wholly independent of sensation or emotion; but it may be likewise produced or kept up by the irritated state of the cord itself. The painful erection of the penis, called *chordee*, which occurs in cases of inflammatory gonorrhœa, is partly a reflex phenomenon, but is chiefly due to a change in the circulation of the penis, to an increased attraction of blood to the organ in virtue of the inflammatory state.

Enough has been said to shew that, to lay it down that every act of ingestion, of retention, of expulsion, and of exclusion, is a reflex act, is opposed to all that we know of the intimate nature of these actions. The power resident, not in the spinal cord only, but in every nervous centre in which nerves are implanted, whereby, to use Prochaska's words, sensory impressions may be converted into motor impulses, is no doubt of immense importance to the animal economy; but Dr. M. Hall has been evidently led, by an imperfect analysis of the functions we have been considering, to assign to this power too large an influence in them; and on the other hand, he has overlooked its obvious and important influence in other phenomena.

Dr. Marshall Hall also attributes to the spinal cord a direct action or influence which manifests itself, first, in the tone, and secondly, in the irritability of the muscular system.

I regret to be compelled to differ again from Dr. Hall with respect to this point, and to express my opinion that this dogma is inconsistent with established doctrines of physiology.

By the *tone* of the muscular system, I understand that state of passive contraction which every healthy muscle exhibits when not in active contraction. It is this state which gives the firm, resisting, resilient feel, which the physician knows to be characteristic of a healthy state of the muscle. By virtue of it a muscle can adapt itself to changes which may take place in the distance between its two points of attachment; and it is in virtue of this property that a muscle shortens itself when the stretching force of its antagonist has been removed. When the muscles of one side of the face have been paralysed for some short time, the features lose their balance, because the muscles of the sound side have contracted to within a smaller space, having lost the resistance of those of the opposite side. It is equality of tone which preserves the equilibrium between symmetrical muscles; it is tone or passive contraction which keeps hollow muscles quite closed, if they are empty, or firmly contracted on their contents, if not so, as the heart and intestine; the tone of the predominant flexor muscles keeps limbs, whilst at perfect rest, in a semi-flexed position; it is tone which keeps sphincter muscles in a closed state.

The question is, do the muscles derive their state of tone from the spinal cord, and is this property dependent on that organ?

This question is answered in the negative, if we can shew that there are good and sufficient grounds for affirming that muscles possess within themselves all the conditions necessary for the generation of their proper force. That muscles do enjoy these conditions is manifest from the following considerations: 1. their peculiar chemical composition, their main constituent being *fibrine*, a substance which, we know from the phenomena of the coagulation of the blood, exhibits a remarkable tendency to contract; 2. their anatomical constitution; the arrangement in fibres, the intimate texture of those fibres, which in the muscles of the greatest power, the voluntary muscles, is highly complicated; 3. from the large quantity of blood sent to muscles, which are probably more freely supplied with that fluid than any other texture in the body, and which receive it in the greater quantity when that contractile power is more active; 4. from the fact pointed out by Mr. Bowman, that a single muscular fibre, entirely deprived of all nerves, may be made to contract by a slight stimulus applied to any part of it; 5. from the knowledge which we now possess that the mechanism of these actions may be seen by the microscope even in detached portions of muscular fibres; 6. from the fact that muscles dissociated from the nervous centres by the section of all the nerves distributed to them, retain their power of contraction for a very considerable period, long after the nerves which sink into them have lost their excitability.

All these points afford the highest degree of probability that there is no direct dependence of muscle upon the nervous centres for the developement of its proper force; and that this force is the result of the nutrient actions of muscle. The only way in which the nervous system can be said to have an influence upon the muscular force is by promoting the actions of the muscles, and thereby their nutrition. If a muscle have its nerves divided, and be left to itself, its nutrition fails after a certain period, and its contractility with it; but if it be exercised daily by galvanic stimulation, its nutrition remains unimpaired, and its contractility likewise.

The tone of a muscle is nothing but the effect of the continuous developement of the muscular force resulting from the natural changes in the muscle; it is this state of tension which denotes that these changes are actively proceeding, and that a uniform degree of attraction is being exerted between all the parts of the muscular fibre, in a degree proportionate to their masses, and that by this the muscles are maintained in a uniform state of tension so long as they are undisturbed by stimuli conveyed to them through the nervous system, or from some other source.

It seems, therefore, as reasonable as any proposition in physiology, to affirm that the passive contraction or tone of muscles is due to a property inherent in the muscular tissue itself, and dependent solely on its proper nutrition, and that it is not derived from any other tissue. And if this be true, it is clear that the spinal cord cannot be the source of the tone of the muscular system.

This statement is confirmed by the result of the experiment of removing the whole spinal cord in frogs or other animals. When this has been done, the limbs of the animal fall quite flaccid, the muscles being no longer capable of preserving that degree of *active* contraction which is necessary to maintain attitude. A decapitated frog will continue in the sitting posture through the influence of the spinal cord, but, immediately this organ has been removed, the limbs fall apart from the loss of the controlling and co-ordinating influence of the nervous centres. And careful examination of the muscles in such a case as this will show that the molecular phenomena which characterise passive contraction continue in the muscular fibres. The state of *rigor mortis*, which is analogous to that of tone, comes on just as readily in animals which have been deprived of the brain and spinal cord, as in those in which these centres have been undisturbed before death. In short, healthy nutrition supplies all the conditions necessary for the maintenance of tone or passive contraction; nor is the spinal cord (although itself healthy) able to preserve the tense condition of the muscles, if they are not well nourished.

These remarks apply equally to Dr. Hall's doctrine, that the spinal cord is a direct source of irritability to the muscular system. The same arguments which prove that tone is not derived from it are of equal weight with reference to irritability.

It cannot be admitted as an argument in favour of the view which derives muscular irritability from the spinal cord, that muscles lose their firmness and waste, when they have been for some time separated from their proper nervous connections. They suffer, in this way, merely for want of a proper amount of exercise, which they cannot obtain in consequence of the influence of the will being cut off from the limb. If, however, the paralysed limb be exercised artificially, as by the galvanic current, their nutrition and their plumpness may be preserved. For this important observation we are indebted to Dr. John Reid, who likewise called attention to the confirmatory fact, that, in those palsies with which there is combined more or less of irritation of the nervous centre, the muscles do not suffer so much in their nutrition, in consequence of the exercise they undergo in the startings so frequently excited in them by the central irritation. This is not unfrequently seen in cases of paraplegia from irritant disease of the spinal cord.

The supposition that the spinal cord might be the source of irritability to the muscles led Dr. Hall to the very extraordinary inference, that in hemiplegic paralysis, in which the influence of the brain is cut off from certain muscles, while that of the cord remained, *the irritability of those muscles becomes augmented*. He arrives at this conclusion by the following line of argument: assuming the cord to be the source of the irritability of the muscles, the brain may then evidently be looked upon as the exhauster of that irritability in the voluntary actions; if, then, the influence of the brain be cut off, it naturally follows that, as the great agent of exhaustion has lost its power, the irritability, which is ever, as it were, flowing from the cord, will accumulate in the muscles. From numerous experiments I am enabled to state that in nearly all the cases of hemiplegic paralysis from cerebral lesion there is no evidence of any augmentation of the irritability of the muscles of the palsied limbs. If the readiness with which they will respond to the galvanic stimulus be taken as a test, it may on the other hand be stated very confidently that there is evidence of the *diminution* of the irritability of the paralysed muscles, for in nearly all these cases the same current being passed through both sound and palsied limbs at the same time, the latter have contracted either not at all or with very little power as compared with the healthy limbs.

But there are exceptions to this: in some cases (and only in those in which there is more or less rigidity of the paralysed muscles) these muscles respond to the galvanic stimulus with more force and readiness than the sound ones. In these cases the palsied muscles are kept in a state of excitement by some irritant disease within the cranium, and this constant condition of more or less active contraction augments the nutrition, and therefore the irritability of the muscles.

It seems, however, most probable that in all the cases of paralysis, the excitability of the muscles to the galvanic stimulus is dependent not so much upon any change in the condition of the muscles themselves as upon the state of the nerves. If the nervous force in the nerves on the palsied side be depressed, the galvanic stimulus will produce little or no effect upon the muscles of that side, whilst those of the other side will be distinctly excited: but should the nerves participate in any excitement propagated to them from disease within the cranium, as in red softening, or an irritating tumor, or a contracting cyst, they will then respond to the galvanic current more readily than those of the opposite side.*

I have thus endeavoured to show that the spinal cord is a centre of nervous actions, *mental* and *physical, to all parts which derive nerves from it*, the mental actions, however, requiring its association with the brain. Whatever physical nervous actions occur in parts whose nerves are spinal, must be referred to *the cord alone*; and whatever mental nervous actions occur through the agency of spinal nerves must be referred to the *cord in conjunction with the brain*.

Of the office of the columns of the cord.—I shall now inquire whether the parts into which the anatomist can divide the spinal cord have special functions. These parts are, on each side of the median plane, an antero-lateral column and a posterior column. It has been a very prevalent opinion that the antero-lateral column corresponds in function with the anterior roots of the spinal nerves, and that the posterior column corresponds with the posterior roots. This doctrine might have had a good foundation if it could be proved that the posterior or sensitive roots were implanted solely in the

* I have discussed this subject more at large in a paper presented to the Royal Medico-Chirurgical Society in June last, and which will appear in the forthcoming volume of its Transactions. August, 1847.

posterior, and the anterior roots solely in the anterior columns. Nothing, however, is more certain than that both roots are implanted in the antero-lateral columns, and it is extremely doubtful that the posterior roots have any connection at all with the posterior columns. Hence, as far as anatomy enables us to judge, this distinction of function between the two columns cannot be admitted. On the contrary, anatomy indicates that the antero-lateral columns are compound in function. Their connection with the corpora striata and optic thalami, and with the mesocephale through the anterior pyramids and fasciculi innominati, their reception of both the anterior and posterior roots, and their size in each region of the cord bearing a direct proportion to that of these roots, denote that these columns with the associated vesicular matter are the seat of the principal nervous actions, both mental and physical, with which the cord is concerned.

This view of the office of the antero-lateral columns is confirmed by comparative anatomy, which shows that the bulk of the organ or the variety in the size of its various parts depends mainly on these columns.

Pathological observations are also in favour of this doctrine. They distinctly denote that lesion of the antero-lateral columns impairs the sensitive as well as the motor power to an extent proportionate to the amount of lesion. It is worthy of note, however, that while a slight lesion of the cord appears sufficient to impair or destroy the motor power, it requires a considerable extent of injury or disease to impair in any very marked degree the sensitive power. Some lesions of these columns destroy the physical nervous actions of the diseased or injured part of the cord—augmenting those of the portion below the seat of lesion, doubtless by increasing its polarity; this is seen especially in cases of injury to the cord by fractures or dislocations of the spine.

Direct experiments afford no aid in determining the functions of the columns of the cord. Attempts to expose this organ either in living or recently dead animals are surrounded with difficulties, which embarrass the experimenter and weaken the force of his inferences, if, indeed, they afford any premises from which a conclusion may be drawn. The depth at which the cord is situate in most vertebrate animals, its extreme excitability, the intimate connection of its columns with one another, so that one can scarcely be irritated without the others being affected, the proximity of the roots of its nerves to each other, and the difficulty, nay the impossibility, of stimulating any portion of the cord itself without affecting either the anterior or the posterior roots, are great impediments to accurate experiments, and sufficiently explain the discrepancies which are apparent in the recorded results of experiments undertaken by various observers. Moreover, the resultant phenomena, after experiments of this kind, are extremely difficult of interpretation, especially with reference to sensation. "The gradations of sensibility," remarks Dr. Nasse, "are almost imperceptible; the shades are so delicately and so intimately blended, that every attempt to determine the line of transition proves inadequate. There is a great deal of truth in an expression of Calmeil, that it is much easier to appreciate a hemi-paralysis of motion than a hemi-paralysis of sensation. If the anterior fasciculi of the cord possess sensibility but only in a slight degree, the mere opening of the spinal canal and laying bare the cord must cause such a degree of pain as would weaken or destroy the manifestations of sensibility in the anterior fasciculi. This has not been sufficiently attended to by experimenters. Again, the practice of first irritating the posterior fasciculi, and afterwards the anterior, must have had considerable effect in producing the same alteration. It is plain, that in this way the relation which the anterior fasciculi bear to sensation must be greatly obscured; yet, with the exception of some few experiments, this has been the order of proceeding generally adopted."*

All the experimenters agree in attributing to the antero-lateral columns more or less power of motion, but we gain no satisfactory information from this source respecting their sensitive power, and probably for the reasons so well expressed by Nasse in the passage above quoted. But, indeed, we do not need the appeal to experiment in reference to this question, although, if a distinct and unequivocal response could be elicited by means of it, the additional evidence would be of great value.

There is great difficulty in determining precisely the functions of the posterior columns of the cord.

Both anatomy and comparative anatomy are opposed to the view which assigns them sensitive power. In the first place, as already stated, there is no evidence to show that the posterior roots of the spinal nerves are connected with them; even Sir C. Bell, who once held that these columns were sensitive because the sensitive roots were connected with them, gave up that view, having satisfied himself that no such connection existed.† Secondly, if they were sensitive, it is not unreasonable to expect that they would exhibit an obvious enlargement at the situations which correspond to the origins of the largest sensitive nerves; so little, however, is this the case, that the posterior columns exhibit little or no variation of size throughout their entire course. Thirdly, the researches of the morbid anatomist afford evidence unfavourable to the assignment of the sensitive function to these columns. Cases are on record which show that disease of the posterior columns does not necessarily destroy sensibility; that perfect and even acute sensibility is compatible with total destruction of the posterior columns in some particular region, the posterior *roots* remaining intact: and others

* Nasse, Untersuchungen zur Physiologie und Pathologie, Bonn, 1835-36. The passage is quoted from an abstract of the work published in the Brit. and For. Med. Review, vol. iv.

† See his paper on the relations between the nerves of motion and of sensation and the brain. The Nervous System, p. 234. 8vo ed., 1844.

have occurred in which sensibility has been impaired or destroyed, while the posterior columns remained perfectly healthy. In a remarkable case related by Dr. Webster, there was complete paralysis of motion in the lower extremities, but sensibility remained; yet there was total destruction of the posterior columns in the lower part of the cervical region. Dr. Webster did me the favour to allow me to examine the spinal cord in this case, and I was struck with the complete solution of continuity of the posterior columns in the region of the neck: it was impossible in this case that the nervous force could have travelled along the course of these columns, whether from above downwards, or from below upwards. Such a case as this shows distinctly that sensation may be enjoyed in the inferior extremities *independently of the posterior columns*, and if it does not prove that these columns are not the ordinary channels through which sensitive impressions are conveyed to the brain from parts supplied by spinal nerves, it at least shows that there must be some other channel besides them for the transmission of sensitive impressions.

Other cases to the same purport are on record. Mr. Stanley published an account of a case of this kind in the twenty-third volume of the Medico-Chirurgical Transactions. He states, "there was no discoverable impairment of sensation in any part of either limb: on scratching, pricking, and pinching the skin, nowhere was any defect of feeling acknowledged by the patient. In the upper limbs there existed no defect, either of motion or sensation." There was inability to expel the urine or retain the fæces. The report of the post-mortem appearances in this case is not quite so exact as might be desired. The posterior half of the cord and the posterior columns are spoken of as if synonymous; now it is evident that the posterior half of the cord consists of a great deal more than the posterior columns; it includes the posterior part of the antero-lateral columns. The record of the case states as follows: "The substance of the cord throughout its posterior half or column, and in its entire length, from the pons to its lower end, had undergone the following changes of colour and consistence; it was of a dark brown colour, extremely soft and tenacious. The substance of the cord through its anterior half and entire length exhibited its natural whiteness and firm consistence; and on making a longitudinal section of the cord through its centre, and in the antero-posterior direction, the boundary line between the healthy and diseased nervous matter was seen to be most exact: it was a straight and uninterrupted line from the pons to the lower end of the cord. The roots of the spinal nerves were unaltered."

Supposing that the posterior columns are the media of sensation to parts supplied by spinal nerves, we can by no means infer that the lesion in this case recorded by Mr. Stanley was sufficient to *destroy* sensation; it cannot, however, be conceded that, if this view were correct, such a lesion could exist without impairing sensation in some way or other, inasmuch as the whole of the posterior columns were involved in a notably diseased condition.

The following case is related by Cruveilhier. A young amaurotic girl, paraplegic of movement only, died from some unknown cause. The spinal cord presented on its posterior surface in its entire length a large reddish-grey (gris-rosé) column, formed by the posterior columns. All the rest of the cord was perfectly healthy.

In a case recorded by Dr. Wm. Budd it is stated that the lower extremities were quite deprived of motion, "but with sensation unaffected." The disease was the result of a severe blow on the back from the boom of a ship, which led to a curvature of the spine, formed by prominence of the dorsal vertebræ from the fourth to the ninth inclusive. After death a portion of the cord, about two inches in length, corresponding to the curvature, was found softened in the posterior columns. The tissue was not diffluent, but became flaky and partially dissolved when a small and gentle current of water was poured on it. In this case, no more than in that of Mr. Stanley, the lesion was not enough to *destroy* sensation, but surely it was sufficient to *impair* it, if the posterior columns are to be regarded as the channels of sensation.*

Serres records the case of a woman who had been paraplegic for two months: sensibility was preserved in the lower extremities; the lesion consisted in disease of the posterior columns of the cord below the middle of the dorsal region.†

In two cases which occurred in King's College Hospital under my own care, the prominent symptom was impairment of the motor power, without injury to the sensitive; yet the seat of organic lesion in both was in the posterior columns of the cord.

Nasse, in the paper before referred to, alludes to several cases of the same nature, in which disease affected the posterior columns, but did not impair sensation.

Longet, who is a warm advocate for the identity of function between the posterior *roots* and posterior *columns*, cites some instances in which total loss of sensibility coexisted with degeneration of the posterior columns as the only lesion: in these cases, however, the posterior *roots* of the nerves were involved in the disease, and their function became impaired or destroyed in consequence. A case of this kind, to be conclusive upon the point in question, ought to exhibit complete destruction of the posterior columns, or of a considerable portion of them, with perfect integrity of the posterior roots and of the antero-lateral columns. If in such a case there were total loss of sensibility in the parts in nervous communication with the diseased portion of the spinal cord, then, indeed, we would be justified in affirming that the antero-lateral columns took no part in propagating sensitive impressions, and that the loss of sensibility was due to the morbid state of the posterior columns.

* Med.-Chirurg. Trans., vol. xxii.

† Anat. Comp. du Cerveau, vol. ii., p. 221.

When to these results, obtained from pathological researches, we add those of experiment, nothing is gained which can be favourable to the attribute of sensitive power to the posterior columns of the cord. Dr. Baly's experiments on tortoises showed that movements might be excited whether the anterior or the posterior columns were irritated, much stronger motions being excited by the posterior than by the anterior columns. Longet found that motions might be excited by irritation of the posterior columns of the cord if the experiment had been made immediately after the transverse division of the cord, and he refers such motions, probably with justice, to an excited state of the cord. After a little time this subsides, and then M. Longet was able to pass the galvanic current through each or both of the posterior columns, without exciting any motions when the lower segment of the cord was acted upon, but causing pain, as evinced by loud cries and writhing of the body, when the upper segment was tried. From experiments of this kind no satisfactory deductions can be made: to irritate the posterior columns of the spinal cord in a living dog without affecting in some degree the posterior roots of the nerves, appears to me to be quite impossible, even in the hands of the most practised vivisector.

Neither anatomy, pathological observation, nor experiment, lend sufficient countenance to the doctrine of the identity of the function of the posterior roots and posterior columns to justify us in concluding that these columns are the ordinary channels for the transmission of the sensitive impressions made upon the trunk and extremities.

I have long been strongly impressed with the opinion that the office of the posterior columns of the spinal cord is very different from any yet assigned to them. They may be in part commissural between the several segments of the cord, serving to unite them and harmonize them in their various actions, and in part subservient to the function of the cerebellum in regulating and co-ordinating the movements necessary for perfect locomotion.

This view is suggested by a comparison of the spinal cord with the brain, and by the anatomical connections of the posterior columns.

The brain is an organ composed of various segments, which are connected with each other by longitudinal commissures. The cord is obviously divisible into a number of ganglia, each forming a centre of innervation to its proper segment of the body. These portions must be connected by similar longitudinal commissures to those which confessedly exist in the brain. If we admit such fibres to be necessary to ensure harmony of action between the several segments of the encephalon, there are as good grounds for supposing their existence in the cord as special connecting fibres between its various ganglia to secure consentaneousness of action between them.

The attribute of locomotive power rests upon the connection of the posterior columns with the cerebellum, and the probable influence of that organ over the function of locomotion and the maintenance of the various attitudes and postures. If the cerebellum be the regulator of these locomotive actions, it seems reasonable to suppose that these columns, which are so largely connected with it, each forming a large proportion of the fibrous matter of each crus cerebelli, should enjoy a similar function, and that, as they are the principal medium through which the cerebellum is brought into connection with the cord, it must be through their constituent fibres that the cerebellum exerts its influence on the centre of innervation to the lower extremities and other parts concerned in the locomotive function, and on the nerves distributed to these parts.

The nearly uniform size of the posterior columns in the different regions of the cord, whilst it may be noted as unfavourable to their being viewed as channels of sensation, may be adduced as a good argument in favour of their being concerned in locomotion and acting as commissural fibres. It is a fact worthy of notice that these columns experience no marked diminution in size until the large sacral nerves, which furnish the principal nerves of the lower extremities, begin to come off. The reason of this is probably because the fibres of these columns connect themselves in great part with the lumbar swelling of the cord, and some of them perhaps pass into the sacral nerves.

The following remarks will serve to explain the manner in which the posterior columns may contribute to the exercise of the locomotive function. In examining a transverse section of the cord in the lumbar region, we observe a great predominance of its central grey matter; the posterior columns appear large, and the antero-lateral columns seem inadequate in proportion to the large roots of nerves which emerge from it. Now, an analysis of the locomotive actions shows, with great probability, that they are partly of a voluntary character, and partly dependent on the influence of physical impressions upon that segment of the cord from which the nerves of the lower extremities are derived. There are two objects to be attained in progression, namely, to support the centre of gravity of the body, and to propel it onward. The former object is attained by physical nervous actions, the latter by mental. The support of the centre of gravity of the body requires that the muscles of the lower extremities, the pillars of support to the trunk, should be well contracted in a degree proportioned to the weight they have to sustain. The contraction of these muscles seems well provided for in an arrangement for the developement of nervous power by a stimulus propagated to the centre, and then reflected upon the motor nerves of these muscles. The stimulus is afforded by the application of the soles of the feet to the ground; it is therefore proportionate to the weight which presses them downwards. It is well known that reflex actions are more developed in the lower than in the upper extremities, and the surface of the sole of the foot is well adapted for the reception of sensitive impressions. No object can be assigned for this peculiarity, unless it have reference to the locomotive actions, and the great developement of the vesicular nervous matter in these regions betokens the frequent and energetic evolution of the nervous force. All the structural arrangements necessary for this purpose are found in the antero-lateral columns. The posterior columns come into exercise in balancing the trunk and in harmonizing its movements with those of the lower extremities.

Some support is obtained for this view of the function of the posterior columns from the phenomena of disease. In many cases, in which the principal symptom has been a gradually increasing difficulty of walking, the posterior columns have been the seat of disease. Two kinds of paralysis of motion may be noticed in the lower extremities, the one consisting simply in the impairment or loss of the voluntary motion, the other distinguished by a diminution or total loss of the power of coordinating movements. In the latter form, while considerable voluntary power remains, the patient finds great difficulty in walking, and his gait is so tottering and uncertain that his centre of gravity is easily displaced. These cases are generally of the most chronic kind, and many of them go on from day to day without any increase of the disease or improvement of their condition. In two examples of this variety of paralysis I ventured to predict disease of the posterior columns, the diagnosis being founded upon the views of their functions which I now advocate; and this was found to exist on a post-mortem inspection; and in looking through the accounts of recorded cases in which the posterior columns were the seat of lesion, all seem to have commenced by evincing more or less disturbance of the locomotive powers, sensation being affected only when the morbid change of structure extended to and more or less involved the posterior roots of the spinal nerves.

Bellingeri put forward the opinion that the anterior columns of the spinal cord influenced movements of flexion, and the posterior columns those of extension; to the grey matter he assigned the office of propagating sensitive impressions to the brain; and the lateral columns, according to him, exercised an influence upon the organic functions of nutrition and circulation.

The views already referred to respecting the grey matter show that it cannot be regarded as devoted exclusively to one function of the nervous system; nor can it be viewed as capable of taking its part in nervous actions without the white or fibrous matter.

Valentin adduces some experiments not unfavourable to the supposition that the nerves of extensor muscles pass towards the posterior part of the cord, and those of the flexor muscles to the anterior part. He found that if, in frogs, the posterior surface of the cord on one side of the posterior median fissure in the region of the second or third vertebra were irritated by the point of a needle, the anterior upper extremity of the same side was extended and drawn backwards. When the anterior surface was irritated, the limb was drawn forwards to the head. Irritation of the posterior column in the region of the sixth vertebra and below it caused extension of the posterior extremities, but they were thrown into flexion by irritation of the anterior columns.

These are remarkable results; they need, however, the confirmation of other observers. If they be correct, the fact of the connection of the nerves of extensor muscles with the posterior columns has an interesting relation with the supposed locomotive function, for there can be no doubt that movements of extension contribute largely to the ordinary attitudes and to the various modes of progression.

Valentin refers to cases in which the anterior columns having been the seat of tumor or of softening, more or less permanent flexion of the lower limbs had ensued. These cases do not favour his view unless he can show that the lesion in all the cases was of the irritant kind, inducing a spasmodic contraction of the flexor muscles; for if the lesion be of a paralysing kind, the effect would be to paralyse the flexor muscles and allow the extensors full sway. The explanation of the flexed state of limbs in cases of this kind is probably to be derived from a chronic state of contraction induced in the muscles themselves by the lesion of the nervous centre, and the state of flexion is assumed rather than extension in consequence of the predominance of flexor muscles over extension.

Sir Charles Bell's doctrine, which assigned to that portion of the cord which is intermediate between the roots of the nerves, (*his middle column,*) a special power over the movements of respiration, has long ceased to gain attention from physiologists. It wanted the support of anatomy. The so-called middle column had no defined limits, nor could it be proved that any respiratory nerves were connected with this region of the cord, excepting a few fibres of the spinal accessory nerve. The distinct anatomy of a respiratory system of nerves existed only in the imagination of the inventor of the doctrine. It could not be shown by experiment that the so-called nerves of respiration had any special respiratory function beyond that which they exercised as the motor nerves of certain muscles. And among the nerves which Sir C. Bell had classed together as nerves of respiration, were some which certainly had no necessary connection with that function. Of these the portio dura and the glosso-pharyngeal are examples.

Influence of the spinal cord upon the organic functions.—The influence of the spinal cord upon certain organic functions has engaged a large share of the attention of experimental physiologists. It has been said to have a very direct control over the functions of circulation, calorification, secretion, especially that of the kidneys.

If it can be shown that the organs concerned in these functions receive several nerves from the spinal cord, then we do not stand in need of vivisections to indicate to us that the functions with which they have to do are, to a certain extent at least, influenced by this organ. Now it is almost certain that the heart and kidneys receive filaments from the cord which pass to them chiefly in the sympathetic nerve; but as it is equally certain that they receive nerves from other sources likewise, as from the vagus nerve, and the proper filaments of the sympathetic, it would be erroneous, so far as anatomy teaches us, to affirm that these organs were wholly dependent on the cord.

As regards the heart, observation and experiment on man and animals tend to confirm the conclusion which anatomy indicates, namely, that while the heart possesses a certain inherent power, and while it has an immediate connection with the medulla oblongata and with the sympathetic, it is also not independent of the spinal cord. A slight injury to the cord or a chronic lesion of it affect the heart but little or not at all, because of its other sources of innervation; but a sudden and extensive injury to the cord, or a rapidly-developed destructive disease of it, materially depresses and weakens the action of the heart, and thereby the general circulation. The experiments of Clift, Wedemeyer, and Nasse may be cited as leading distinctly to this conclusion. Nasse's experiments were on dogs, in which he maintained artificial respiration; he found that as soon as the spinal cord was destroyed, the heart failed so completely that the jet of blood from the femoral artery, which before had gone to a distance of some feet, could not reach as many inches, or the blood did not escape per saltum from the wounded artery. In performing a similar experiment, Longet compared the action of the heart in two dogs, destroying the cord in one, but allowing it to remain intact in the other, and he found that in the animal whose spinal cord was destroyed the cardiac movements became enfeebled in a very striking manner, when compared with those of the animal whose cord was left uninjured.

If, then, we can prove that the spinal cord exercises an influence upon the central organ of the circulation, there can be no doubt that its power extends to the peripheral parts of the circulating system, to the capillary vessels, and, therefore, that injury or disease of it, especially if sudden or extensive, must to a certain extent affect the functions which are performed through the agency of these vessels, namely, nutrition, calorification, and secretion.

It seems most probable that it is only in this secondary manner that the influence of the spinal cord becomes extended to these functions, and that they suffer, when, through lesion of the cord, this influence has been greatly diminished or removed. The indications of its connection with nutrition and calorification are derived from the wasting and the coldness which are manifest in the paralysed parts when there is lesion of the spinal cord of a depressing kind. Sometimes, too, the nutrition of these parts is so feeble that gangrenous sloughs are formed on parts exposed even to slight pressure. This is more apt to be the case where the disease of the cord has been of a destructive kind, and has involved a considerable portion of the organ and of the roots of its nerves.

The influence of the spinal cord upon secretion has been inferred chiefly from the frequent occurrence of an alkaline state of urine in connection with injuries of that organ, and less frequently in diseased states of it. The urine, when passed, is found to be highly alkaline from the existence in it of a large quantity of carbonate of ammonia. The urine, in cases of this kind, is very apt to contain more or less of what has been very commonly, although erroneously, called *ropy mucus*, which is in truth pus formed from the mucous membrane of the bladder. This membrane is irritated and inflamed by the sojourn in it of the urine which the paralysed bladder is unable to expel. The secretion of a large quantity of phosphate of lime and of mucus, and afterwards of pus, is provoked by inflammation of the vesical mucous membrane. And the addition of these matters to it, especially the former, neutralises all free acid and gives rise to decomposition of the urea, and the production thereby of carbonate of ammonia. The alkalescence of the urine favours the precipitation of the triple phosphate. Hence urine obtained from patients suffering under spinal disease resembles very closely that of patients with diseased bladder without spinal disease. We may see in it mucus or pus globules, triple phosphates, blood particles, and amorphous masses of phosphate of lime mingled with the mucus. But in some instances the period of the sojourn of the urine in the bladder appears too short for these changes to take place; and hence it has been supposed that the urine may be secreted alkaline by the kidneys. Mr. Smith, of St. Mary's Cray, in Kent, made experiments on this subject by washing out the bladder carefully with warm water several times, withdrawing the water each time and testing for ammonia until all indication of its presence ceased. He then injected a small quantity of clear water, and allowed it to remain fifteen or twenty minutes; it was then drawn off, and the odour of ammonia could be distinctly perceived. It is to be regretted that a more accurate test of the presence of ammonia had not been used. Admitting, however, that ammonia did exist in this fluid, the experiment by no means disproves the formation of ammonia in the bladder. So small a quantity of urine as might trickle into the bladder in twenty minutes might readily be neutralised and decomposed by any alkali or mucus present in the bladder which might have eluded the previous washing out of that organ. If the secretion of urine in the alkaline state were common, it might reasonably be expected that such urine would be more frequently met with than it is in spinal complaints. Dr. Golding Bird, indeed, states that in the case of a woman in Guy's Hospital, labouring under complete paraplegia, and passing, with the aid of a catheter, fetid, alkaline, and phosphatic urine, he washed out the bladder with warm water, and after the lapse of half an hour obtained some urine from the bladder by the catheter; this he found to be acid, a sufficient proof that the urine was not alkaline when secreted, but underwent the change during its stay in the bladder.

In those affections of the spine which are not attended by a paralysed state of the bladder, the urine is not alkaline; let, however, the power of the bladder be impaired, even to a slight degree, and the quality of the urine will soon suffer. And it is well known that in cases where impediment to the flow of urine from the bladder occurs independently of any paralysis of the organ, as from stricture of the urethra, a similar derangement in the quality of the urine is apt to take place.

It must not, however, be forgotten that chronic disease of the brain or spinal cord is frequently accompanied by phosphatic urine, even when the power of the bladder is unimpaired, and that in such urine the addition of a little liquor ammoniæ or potassæ will cause a more or less copious precipitate of triple phosphate. There can, therefore, be no doubt that the cerebral or spinal lesion affects in some way or other the renal secretion so as to favour the developement of alkaline phosphates in it, and thus to create a tendency to its becoming alkaline. This, however, may arise not from any special influence upon the kidney, but from an undue waste of nervous matter, which would furnish the material for the formation of the phosphatic salt.

A very striking connection between the spinal cord and the kidneys, whereby a diseased state of the latter organs induces a functional derangement of the former, is shown by the history of those cases to which the attention of medical men was first called by Mr. Stanley. The patients are more or less completely paraplegic, and all the symptoms of disease of the spinal cord exist: but at the same time there exists irritation or actual organic lesion of the kidneys, which, however, may be overlooked or attributed to the spinal disease. When the renal disease has been completely removed and the kidneys restored to their normal condition, the paralysis gets well; but more frequently both the renal disease and the paraplegia resist all remedial means, and the patients die. On examination, both the brain and spinal cord are found perfectly free from any organic lesion; but distinct evidence of inflammatory or other irritant disease of the kidneys exists.*

In a case of this kind which came under my own observation, there was, along with complete paralysis of sensation and motion in the lower half of the body, excessive hæmaturia, which had all the characters indicative of renal hemorrhage. From the man's habits and history I suspected that the affection of the kidney had something to do with suppressed gout, and accordingly I used every means to attract gout to the feet. These means were successful, for, no sooner was my patient attacked with an active paroxysm of gout in one great toe than the renal disease began to subside, and the paralytic affection disappeared simultaneously.

Rayer, in his valuable work on diseases of the kidneys, relates several cases, which, in addition to those put on record by Mr. Stanley, leave no room to doubt that renal irritation may be propagated to the cord, and may occasion such an amount of disturbance of the functions of that organ as to give rise to paralysis of the lower extremities.

There seems no other mode of explaining these cases than by ascribing them to irritation of the cord excited by irritation of the kidneys, the nerves of the latter organ being the medium through which the renal affection excites the spinal. Yet there is no special connection between the nervous system of the kidney and the spinal cord, excepting probably through such tubular fibres as may be found in the renal plexus. These probably run a short course, and their origin in the cord is in close proximity to their distribution in the kidney; and on this account they may be more obnoxious to the influence of irritant disease of the latter organ.

The power which irritation of the cord has to develope erection of the penis may be here noticed as a remarkable instance of the influence of that organ over a local circulation. For it is only by assigning it to a temporary turgescence of the complex vascular system of the penis that we can explain this erect state. Even in ordinary erection, excited by a stimulus applied to the glans, as already pointed out, the influence of the cord is called into action, and the phenomenon is produced by a reflex, or what Dr. M. Hall would call an excito-motor act. Yet, (and here we may notice how ill-chosen has this term "excito-motor" been,) there is in reality no excitation of muscular action, but the influence of the stimulus propagated to the spinal cord is extended by a reflex act to the nerves which are distributed to the vessels of the penis, and they, instead of being excited to any contraction, become rather relaxed, and are thus prepared to receive a larger supply of blood; or by the extension of this excited influence of the cord, the attractive force (vis a fronte) of the capillaries is increased, and thus a larger quantity of blood is attracted to the organ, and erection takes place. The influence of the nervous system on this act is shown by the most convincing evidence—by the highly sensitive state of the organ, especially of the glans; by the large size of its nerves; by the effects of injury or disease affecting the cord immediately, or by extension from some part of the encephalon; and lastly, by the experiment of Günther, who divided the nerves on the dorsum of the penis in a stallion, and thereby destroyed the power of erection, although the vessels were uninjured.

On the mechanism of the functions of the cord.—Having shown that the spinal cord is concerned in voluntary motions and in sensation, (mental nervous actions,) and in certain reflex actions, as well as in certain organic functions, (physical nervous actions,) it is im-

* Med. Chir. Trans. vol. xviii.

portant to ascertain what is *the mechanism* by which these various actions take place.

The most convenient way to discuss this point will be to examine into the value of certain hypotheses which have been framed to explain it. We shall find it necessary in this discussion to keep before us two propositions in favour of which sufficient evidence has already been adduced. These are, 1. That the brain or some part of it is essential to the production of mental nervous actions; in other words, that acts of volition and sensation cannot take place without the brain: and, 2. That the vesicular is the truly dynamic nervous matter, that which is essential to and the source of the developement of all nervous power.

The first hypothesis which we shall notice is one of so much ingenuity that one is tempted thereby to adopt it, and would gladly do so if it were found sufficient to explain the phenomena, and if it were consistent with that simplicity which characterises the mechanism of the body. It originated with Dr. Marshall Hall, and has been advocated by him with great zeal and ability; it may be distinguished as the hypothesis of an *excito-motory system of nerves*, and *of a true spinal cord*, the centre of all physical nervous actions.

This hypothesis may be stated as follows.*

The various muscles and sentient surfaces of the body are connected with the brain by nerve fibres which pass from the one to the other. Those fibres destined for or proceeding from the trunk to the brain pass along the spinal cord, so that that organ is in great part no more than a bundle of nerve fibres going to and from the brain. These fibres are specially for sensation and volition—*sensori-volitional.*

But, in addition to these, there is, according to Dr. Hall, another class of fibres proper to

* I am very desirous that this hypothesis should be stated correctly, as I consider that both physiology and practical medicine are greatly indebted to Dr. Marshall Hall for the attention his labours have awakened to the inherent powers of the nervous system. Nevertheless I have shown in the text that great advances in our knowledge of these powers had been made by certain physiologists of the last century, whose views and researches had been completely or almost forgotten.

I have collected the statement of Dr. Hall's hypothesis in the text chiefly from his later writings. The history of Dr. Hall's labours on this part of physiology, as I gather it from his writings, appears to be as follows:—

In 1832 a paper was presented by him to the Zoological Society, of which, so far as I can ascertain, no other record has been kept than that which is to be found in the printed summary of the Proceedings of that Society. I have not had any opportunity of consulting these proceedings, but find an extract from them printed in Dr. Hall's work entitled Memoirs of the Nervous System, published in 1837. This paper was entitled, "A brief Account of a particular Function of the Nervous System," and its object was to point out the existence of a source of muscular action distinct from all those hitherto noticed by physiologists. The peculiarity of this motion is stated to consist in its being excited by irritation of the extreme portion of the sentient nerves, whence the impression is conveyed through the corresponding portion of the brain and spinal marrow as a centre, to the extremities of the motor nerves. Experiments upon salamanders, frogs, and turtles were detailed, from which Dr. Hall drew the following conclusions: 1. that the nerves of sensibility are impressible in portions of an animal separated from the rest; in the head, in the upper part of the trunk, in the lower part of the trunk; 2. that motions similar to voluntary motions follow these impressions made upon the sentient nerves; and, 3. that the presence of the spinal marrow is essential as the central and cementing link between the sentient and motor nerves.

Other experiments were detailed in this paper upon frogs rendered tetanic by a solution of opium; these showed that in this state the cutaneous nerves became "extremely susceptive, and the motor nerves extremely excitative." Decapitation of a tetanized frog did not destroy the tetanic condition of the trunk and extremities. "The exalted condition of the function of the sentient and motor nerves continued in each part." "All was changed in removing the brain and the respective portions of the spinal marrow."

"These experiments," Dr. Hall continued, "appear to me to establish a property or function of the nervous system, of the sentient and motor nerves, *distinct from sensation and voluntary or instinctive motion.*"

Dr. Hall's next publication appears to have been a paper read before the Royal Society on the 20th of June, 1833. This paper is entitled "*On the reflex function of the medulla oblongata and medulla spinalis.*" Having noticed the conclusion arrived at by Le Gallois, and confirmed by the reporters of the Institute, that section of the spinal marrow in the neck arrests only the respiratory movements, leaving sensation and voluntary motion to remain in the whole body, he points out that the causes of muscular motion may be *centric* or *eccentric* in the nervous system. When the cause is *eccentric*, that is, distant from the nervous centres, Dr. Hall states that the phenomena are due to a peculiar function, which he considers had not previously been understood. Its characteristic is that it is "*excited* in its action and *reflex* in its course; in every instance in which it is excited, an impression made upon the extremities of certain nerves is conveyed to the medulla oblongata or medulla spinalis, and is reflected along other nerves to parts adjacent to, or remote from, that which has received the impression."

"It is by this reflex character," he adds, "that the function, to which I have alluded, is to be distinguished from every other." Yet, curious to say, he assigns to it powers which certainly cannot be excited in the reflex manner. He says, "the reflex function exists as a *continuous* muscular action, as a power presiding over organs not actually in a state of motion, preserving in some, as the glottis, an open, in others, as the sphincters, a closed form, and in the limbs a due degree of equilibrium or balanced muscular action, a function not, I think, recognised by physiologists."

Dr. Hall points out the distinctness of this function from sensation and voluntary motion, and relates experiments on decapitated animals, (snakes, turtles, vipers, toads, frogs, and efts,) to show that the motions which occur in them are not spontaneous but only excited, and that these "excited motions in decapitated animals are dependent upon a principle different from sensation and volition." He then shows the difference between the reflex movements and those arising from irritability, by comparing the motion of the heart, when touched, with that of the glottis of an animal when similarly stimulated. Both movements take place equally after the removal of the brain; but if the medulla oblongata be removed, the contractions of the larynx cease, while those of the heart continue. "The difference consists, then, in the presence of the medulla oblongata, which is essential to the

the spinal cord and to its intracranial continuation, which form a connection with the grey matter of the cord. Of these fibres some are afferent or incident, others efferent or re-

contractions of the larynx, but of which those of the heart are entirely independent. The influence of the stimulus upon the heart is immediate. That of a stimulus applied to the larynx must pass to the medulla oblongata, and be reflected upon the part moved."

The details of further experiments next follow. The author refers to the reflex function the power which the hedgehog has of assuming the form and firmness of a ball.(?) Cases of infants born without brain or cerebellum are referred to in proof of the existence of reflex actions in the young of the human subject. The experiment of dividing the spinal marrow between the nerves of the superior and inferior extremities is described, to show "two modes of animal life; the first being the assemblage of the voluntary and respiratory powers with those of the reflex function and irritability; the second, the two latter powers only;" "if the spinal marrow be now destroyed, the irritability alone remains, all the other phenomena having ceased."

Dr. Hall next shows that the reflex function admits of *exaltation* and *diminution*. Frogs are made tetanic by opium and strychnine, and the tetanus disappears on removing the spinal marrow. On the other hand, a few drops of hydrocyanic acid placed upon the tongue of a frog depress the reflex function; "the contractions which depend on the reflex function are observed to become less and less energetic and excitable, and at length cease altogether."

Some highly interesting references are made to the light thrown upon the nature of certain diseases by our knowledge of this reflex function. The morbid states produced by dentition, epilepsy, asthma, tenesmus and strangury, tetanus and hydrophobia, are the principal diseases mentioned.

The rest of the paper consists of inferences from the preceding parts and a recapitulation.

Dr. Hall had formed, at this time, no distinct hypothesis respecting any special mechanism for the reflex function. He makes the following remarks, which seem to foreshadow his subsequent hypothesis referred to in the text. "It appears probable," he says, "that the facts of this paper may lead to some important additions to our knowledge of anatomy, by inducing an accurate inquiry into the origin, course, connection, and distribution of the subcutaneous, or submucous, and muscular nerves, which constitute the arcs of the reflex function."

In reviewing this interesting and important paper, it is impossible not to feel the greatest regret that its author should have done so much injustice to himself as well as to those who had preceded him, by neglecting to give an exact account of the state of science in reference to this question at the time he wrote. No one who peruses with candour the essay of Prochaska can deny that it contains, with regard to the reflex function, everything that Dr. Hall's paper contains, everything which will bear the test of careful analysis, omitting those views which are, indeed, peculiar to Dr. Hall, and which do not appear in this paper, assigning to the cord powers over ingestion, egestion, muscular tone, and irritability, &c. Throughout the whole paper no allusion whatever has been made to Prochaska's essay. The Report of certain members of the Institute upon the work of Le Gallois, (both of which Dr. Hall quotes,) makes distinct reference to Prochaska's views of the reflection of sensorial impressions. It must not, however, be forgotten that Prochaska's views had fallen into oblivion and neglect, and that Dr. Hall revived them, illustrated them by experiments, and showed their application to the pathology of the nervous system. I may add, that nothing would be more excusable than that a physician, working at these subjects in 1832, should be ignorant of Prochaska's essay published in 1784, more especially as it was overlooked even by his own countrymen—by such men as Treviranus, Rudolphi, and Müller.

Dr. Hall's next publications, as he himself states, (Preface to Memoirs on the Nervous System, 1837,) were a course of lectures, delivered from a printed syllabus in the summer, and repeated in the winter of 1835, of which one was inserted in the Medical Gazette for January, 1836, and the whole in his Lectures on the Nervous System and its Diseases, published in April, 1836.

It is in this latter work that, so far as I have been able to ascertain, Dr. Hall first put forward the hypothesis detailed in the text. It is stated, however, not as a hypothesis, but as *a discovered fact*. Having described two divisions of the nervous system, the first consisting of the cerebrum and cerebellum with sentient nerves, which pursue their course *to* them, and of motor nerves, which proceed *from* them either along the base of the brain or along the spinal marrow, and then along every external part of the animal frame, and the second comprehending the sympathetic, Dr. Hall goes on to say: "To these two subdivisions of the nervous system, I believe a third must be added before our views of that system can be considered as at all complete; it is one which I claim the merit of first pointing out in all its fullness. Suppose the cerebrum and cerebellum, the *centre* of the first subdivision of the nervous system, and the ganglionic or the second subdivision of this system removed, *this remains*. It consists of the *true* spinal marrow, distinguished from the sentient and motor nerves, which run along its course as an axis of *excitor* and motor nerves. It is the seat of a peculiar series of physiological phenomena, and of a peculiar class of pathological affections." "In the former are included *all* (sic) the functions which relate to the immediate acts of *ingestion* and *egestion*; in the latter, *all* spasmodic diseases." (Loc. cit. p. 11.)

Further on, in the same work, Dr. Hall gives an analysis of his true spinal or excito-motory system, which consists, according to his description, of, 1. the Membranes; 2. the True Medulla; 3. the True Spinal Nerves. The principal divisions of the true medulla, he specifies as follows:

1. The Tubercula Quadrigemina,
2. The Medulla Oblongata,
3. The Medulla Spinalis, and especially its
    1. Cervical,
    2. Dorsal,
    3. Lumbar, and
    4. Sacral portions.*

The reader who has perused with attention the analysis of Prochaska's work given in the text will perceive a striking resemblance between this *true Medulla* and the *Sensorium commune* of Prochaska, p. 721E.

In this work there is no allusion to the important essay of Prochaska, although Sir Charles Bell is corrected for attributing the discovery of the ganglia on the posterior roots of the spinal nerves and on the portio major of the fifth to Monro instead of to Prochaska (p. 17), and two quotations are made from the latter author without specifying the work from which the passages are quoted.

In 1837 Dr. Hall published a quarto volume, with the title, "Memoirs on the Nervous System." This consists of a reprint of the paper published in the Philosophical Transactions, "On the Reflex Function of the Medulla Oblongata and Medulla Spinalis;" and also of a paper which was read

* An anatomical oversight, as the *medulla* spinalis has no sacral portion.

flex, and these two kinds have an immediate but unknown relation to each other, so that each afferent nerve has its proper efferent one, the former being *excitor*, the latter *motor*.

before the Royal Society on February the 16th and 23d, and March the 2d, 1837, but was not published in the Transactions. This paper is entitled, "On the true Spinal Marrow and the Excito-motory System of Nerves."

The object of this paper the author states to be the developement of a great principle in physiology—that of the special function of the true spinal marrow and of a system of excito-motory nerves.

"It is this principle," he continues, "which operates in all those actions which have been designated sympathetic, which regulates the functions of ingestion and expulsion in the animal economy, and which guards the orifices and sphincters of the animal frame."

"The principle to which I allude," he proceeds, "has been confounded with sensation, and voluntary, and what has been designated instinctive, motion, by *all* (sic) physiologists, with one single exception (Sir Gilbert Blane). It has been supposed to be a function of the rational (Stahl) or irrational (Whytt) soul. It has been considered by some (Haller, &c.) as attached to the brain; by others (Whytt, Soemmering, Alison, Muller,) as attached to the brain and spinal marrow; by others (Le Gallois, Flourens, Mayo,) as peculiarly attached to segments of the spinal marrow; it has been viewed by others as the function of the sympathetic (Tiedemann, Lobstein,) or of the pneumogastric nerve (Bell, Shaw); and, lastly, by others as operating through identity of origin or anastomoses of nerves (Mayo)."

How very strange it is that amidst all the research displayed in this paragraph, no mention should have been made of Unzer and Prochaska, the only authors who really had clearly stated the correct doctrine respecting nervous phenomena independent of the mind!!

In this paper Dr. Hall falls into the curious error of affirming that the power which is developed in the nervous system in connection with sensation and volition, is different from that through which the reflex actions are produced. To the latter he limits the term *vis nervosa*, and, having quoted Haller's very correct description of the course which it takes in motor nerves, he affirms that his researches have disclosed a series of phenomena "directly at variance with the conclusions of Haller."

I confess myself quite unable to discover in what respect Dr. Hall's results are at variance with the laws of the vis nervosa as laid down by Haller. All that the latter physiologist affirmed was that the nervous force travelled from trunk to branches in motor nerves, and that irritation of the spinal cord caused convulsions of the limbs which derived their nerves from below the point of stimulation. Now these facts are strictly true—by whatever stimulus the nervous force is excited in motor nerves it travels from trunk to branches; and the statement made by Haller respecting the spinal cord is equally true, namely, that the motor force travels downwards, and that irritation of the cord affects only the limbs below the irritated point. All that Dr. Hall has made out which is at variance with this proposition is, that *sometimes* the anterior extremities may be thrown into action by stimulating that segment of the cord from which the posterior extremities derive their nerves, from whence he concludes that "the motor power in the spinal marrow will act in a *retrograde* direction."

This conclusion, however, does not follow from the experiments adduced in support of it. If the spinal cord of a turtle be irritated in the segment from which the nerves to the hinder extremities spring, and all four extremities are thrown into action by that stimulus, we are not authorized to conclude that the *motor* power will act in the spinal marrow in a retrograde direction; all that we are justified in affirming is that the same change which would excite the nerves of the irritated part of it may be propagated from its lower to its upper part. How this takes place is uncertain, whether by sensitive fibres or by commissural fibres, or by vesicular matter, most probably by the last.

It may, however, be stated that such phenomena as those described take place chiefly in an excited state of the cord, as when the animal is under the influence of strychnine—or in tetanus—and their occurrence is far from being in accordance with a normal state of action of the spinal cord. I have frequently irritated the cord in healthy animals without producing any movements save in parts below the point stimulated. (Vide supra, p. 721G.)

Dr. Hall in this paper draws the same conclusions as in his work last referred to as to the existence of a "*true spinal marrow* physiologically distinct from the chord of intra-spinal nerves; of a system of excito-motory nerves, physiologically distinct from that of the sentient and voluntary nerves; and of a nervous influence—the excito-motory power—operating in directions incident, upwards, downwards, and reflex, with regard to the true spinal marrow, the centre of this excito-motory system." When Dr. Hall uses the term *physiologically* distinct, of course he means, likewise, *anatomically* distinct. One part cannot be *physiologically* distinct from another without being *anatomically* so also.

In the second section of this paper Dr. Hall gives "a slight sketch of the opinions of physiologists upon the subject of this memoir." He alludes to the views of Haller, Monro, Whytt, Blane, Le Gallois, and the Reporters of the Institute upon Le Gallois' Essay, Mayo, Flourens, Alison, and Muller, but makes no allusion to either Unzer or Prochaska.

I pass over the third, fourth, fifth, and sixth sections, and proceed to the seventh. Here the laws of the excito-motory system are stated, and those extravagant powers are attributed to it, which I have in the text endeavoured to show it cannot exercise. But, in addition, this system is made to be the nervous agent of the appetites and passions! What strange confusion! that a system, devised as the special centre of nervous actions *independent* of the mind, should be the seat of phenomena preeminently mental, and intimately connected with sensation.

The remainder of this essay consists of further remarks on the anatomy, physiology, pathology, and therapeutics of the excito-motor system, and concludes with some observations on the ganglionic system of nerves.

In 1841 Dr. Hall published his work on the Diseases and Derangements of the Nervous System. In this work I am not aware that any new or additional fact has been stated not mentioned in those already quoted. It includes a reprint of several memoirs read to the Medico-Chirurgical Society.

In 1843 a "New Memoir on the Nervous System" appeared, dedicated to Professor Flourens as to one "who has in his responsible office displayed the most candid, impartial, and generous judgment of the works of others."

I find it necessary to notice an assertion contained in a note to the advertisement of this work Dr. Hall observes:—

"My first memoir was entitled, 'On the Reflex *Function* of the Medulla Oblongata and Medulla Spinalis.' This important *function* as the nervous agent in *all* the acts of ingestion and of egestion in the animal economy was previously unknown. It is not mentioned by Whytt, or Prochaska, or any other author; who, however they may cite the term reflex, or detail experiments, or treat of sym-

The aggregate of these fibres, together with the grey matter, constitutes the *true spinal cord* of Dr. Hall, which is not limited to the spinal canal, but passes up into the cranium as far as

pathetic actions, have not, I affirm, associated *one physiological act* with any such *reflex function* of the spinal marrow. This is, therefore, my discovery."

Upon this passage I must remark, 1st, that if Dr. Hall merely claims the discovery of the reflex function, it cannot be conceded to him, for Prochaska had already distinctly announced the existence of this function in the medulla oblongata and spinalis, using even the term *functio*, as in the following passage: — "Cum itaque *præcipua functio* sensorii communis consistat in reflexione impressionum sensoriarum in motorias, notandum est, quod ista reflexio vel animâ nesciâ, vel vero animâ consciâ fiat." Loc. cit. pp. 118-19.

If, however, Dr. Hall claims the discovery of this function "*as the nervous agent in all the acts of ingestion and egestion in the animal economy*," then I have only to remark that I know of no physiologist in the present or in former times who would care to dispute such a discovery with him. I have already shown that the id a that these acts of ingestion and egestion are dependent on this function is a fiction of the fancy—an *idolon specus*—which rests upon an imperfect and erroneous analysis of these acts, and on very narrow views of the nature and mode of developement of the nervous force. If, finally, Dr. Hall limits his claims, as he says he might do, to the discovery (?) of the anatomy and physiology of the true spinal system, as a combined system of "1, *incident nerves*; 2, *their spinal centre*; and, 3, *reflex nerves*, constituting the anatomy of the whole series of the acts of ingestion and egestion," I am quite sure that no anatomist or physiologist of the present day would seek to deprive him of such a discovery, or dispute the opinion of Professor Flourens that it belongs to Dr. M. Hall. That this so-called true spinal system is no more than an hypothesis, and one which has but an infirm basis to rest upon, I have endeavoured to show in the text. That a centre of reflex actions exists—but not distinct from the centres of sensori-volitional acts—every physiologist will admit, and the limits of that centre were most correctly defined more than fifty years ago by Prochaska under the name *sensorium commune*, which extends, according to him, "quam late patet nervorum origo," and which, as I have already remarked, completely foreshadowed Dr. Hall's "true spinal marrow."

In sections 5—11 of this work Dr. Hall states the real objects of his researches as follows.

"First, to separate the reflex actions from any movements resulting from sensation and volition.

Secondly, to trace these actions to an acknowledged source or principle of action in the animal economy—the *vis nervosa* of Haller—acting according to *newly discovered laws*.

Thirdly, to *limit* these actions to the *true spinal marrow*, with its appropriate incident and reflex nerves, exclusively of the cerebral and ganglionic systems.

Fourthly, to apply the principle of action involved in those facts to physiology, viz. to the physiology of all the acts of exclusion, of ingestion, of retention, and of expulsion in the animal frame.

Fifthly, to trace this principle of action in its relation to *pathology*, viz. to the pathology of *the entire class of spasmodic diseases*; and,

Sixthly, to shew its relation to *therapeutics*, especially to the action of *certain remedial and certain deleterious physical agents*.

Finally, it is to these objects, taken together as a *whole* or as a *system*, that I prefer my claims; and I do not pretend that an occasional remark may not have been incidentally made by some previous writer, bearing upon some one or other of them."

It is in this work that Dr. Hall has, for the first time, ventured to notice the remarkable views of Prochaska. I wish, for the sake of English physiology, and also for the sake of Dr. Hall's own character as one who professes great admiration for those who "display a candid, impartial, and generous judgment of the works of others," that the extracts which he has made from Prochaska's work, few and imperfect as they are, had been accompanied by some more dignified and more ingenuous remarks than those contained in the following paragraph.

"It is impossible to adduce specimens of more complete confusion than these, in which voluntary acts, and the actions of the *heart, stomach*, and *intestines*—functions of the *cerebral* and of the *ganglionic* systems respectively,—are arranged with certain reflex experimental facts, and *very obvious* sympathetic actions, which really belong to the true spinal system."

I have carefully examined the passages quoted from Prochaska by Dr. Hall, and I confess myself unable to discover any of that "complete confusion to which he alludes." Prochaska states, that numerous examples (plurima exempla) prove the general law of the reflecting power of the sensorium commune, of which, however, he says, it will suffice to adduce only a few. He mentions sneezing produced by irritation of the mucous membrane of the nostrils,* the violent cough produced by irritation of the glottis—per micam cibi vel guttulam potus illapsam,—and the winking excited by bringing the finger close to the eye. If these are not fair examples of reflex actions, I know not what are.

Prochaska then proceeds to show that these reflex actions may take place with or without the cognizance of the mind; and here I must refer to a very disingenuous proceeding on the part of Dr. Hall in his quotations. He displaces the passages from their right order and therefore from the context, and thereby introduces an appearance of confusion which does not exist in the original. The passage commencing "Si amicus digito," &c. occurs before and in a different paragraph from that commencing "Cum itaque præcipuo," &c., Dr. Hall quoting them as if the latter stood first. He has similarly transposed the passages commencing "Sed fieri tamen," &c. and "Motus cordis, ventriculi."

In the remaining portion of this work Dr. Hall has systematized his views more completely than in his previous writings—repeating, however, much the same experiments, re-asserting the same explanations of certain actions as before, and adding some new remarks in vindication of his views already expressed. Yet in this volume there are indications as if Dr. Hall had no great confidence in his own hypothesis, notwithstanding he had thought it worthy of being designated a discovery. At § 149, referring to Dr. Carpenter's and Mr. Newport's opinions in favour of the existence of excito-motory fibres distinct from sensori-volitional fibres, he remarks, "I doubt not that the investigations of these gentlemen are correct; they have, therefore, confirmed *what I had long previously* done." But in § 150, having mentioned Mr. Grainger's assertion that in the roots of the spinal nerves one set of fibres passes up to the brain, while the other pursues its course to the grey matter, he says, "It is probable, therefore, that the former are in reality nerves of sense and voluntary motion, whilst the latter are the nervous channels of the excito-

* Prochaska supposes that the *olfactory* nerves propagate the irritation which excites sneezing to the centre; — the office of the fifth nerve was not made out in his day.

the crura cerebri. (Its extent, indeed, is much the same as that which has been assigned by Prochaska to his *sensorium commune.*) These fibres are quite independent of those of sensation and volition and of the sensorium commune, using that term as indicating the centre of intellectual actions. Although bound up with sensitive and motor fibres, they are not affected by them, and they maintain their separate course in the nerves, as well as in the centres.*

motor power and action. I say it is probable this is the case." And in § 151 he says, "It has always appeared to me that, observing the difference between the cerebrum and the spinal marrow, the olfactory and the trifacial nerves, in regard to the psychical and the excito-motor properties, it is very improbable that in *any* part of the nervous system the two functions should co-exist in any one individual fibre." I am, therefore, not premature in refusing to accept as a discovery that which Dr. Hall himself regards only as *probable* -- and *not proved*. Lastly, at § 370, he quotes an experiment by Van Deen and Stilling, in which *one-half* of the spinal marrow is divided above the origin of the brachial nerves, and the other half below the same point, with the effect of leaving sensation and voluntary motion undestroyed. On this he remarks, "There is, therefore, no continuous rectilinear course of nervous fibre from the brain to the extremities."!!

I shall here contrast the points made out by Prochaska with the statement of Dr. Hall's "real objects" as quoted a few paragraphs back.

1. Prochaska forms a large estimate of the importance of the vis nervosa; he attributes to it a high place among the forces which concur in the production of vital phenomena—not limiting the term, as Haller did, to the force by which nerves excite muscles to contract, but viewing it as THE agent in the production of all the phenomena of the nervous system.

2. He investigates the *laws* of this force as it is developed in the pulp of the nerves, leaving the enquiry into its *nature* to those who are engaged with physical experiments.

3. He shows that this nervous force, although in truth an innate property of the medullary pulp, nevertheless needs a stimulus for its developement.

4. This stimulus, he further shows, may be either physical or mental.

5. He investigates the causes and effects of the increase and of the diminution of the vis nervosa, and how it is influenced by age, sex, and temperament.

6. He shows that the nervous force remains in nerves separated from the centres (within certain limits) even in "singulis dissectorum nervorum frustis."

7. Prochaska lays down that nerves act in producing motion and sensation in virtue of their power of propagating impressions made on them, whether at their origin or at their periphery.

8. He shows that external impressions made upon sensitive nerves are quickly propagated to their origin and there are *reflected*, according to a certain law, into corresponding motor nerves, whereby certain definite motions are effected.

9. This takes place whenever motor and sensitive nerves are implanted in the neighbourhood of each other, and all that part of the cerebro-spinal axis in which nerves are so implanted is called by Prochaska *sensorium commune.*

10. This reflexion of sensitive impressions into motor ones is a *physical phenomenon* independent of the mind.

11. The mind, however, may or may not be conscious of its occurrence.

12. Examples of reflex acts of this kind are found in sneezing, in the winking of the eye when the finger is suddenly directed close to it, in the violent cough produced by a particle of food or a drop of water passing into the trachea. In all these instances the effects of the stimulus applied to the sentient nerves of the part irritated are propagated to the centre, and there reflected into the nerves of those muscles by which the respective movements are produced.

13. The motions which may be produced in decapitated animals by excitation of the surface are of this kind, the reflexion taking place in the *residual portion* of the sensorium commune, which is in the spinal marrow; and those produced in patients labouring under apoplexy are of the same kind.

14. A similar reflexion takes place in ganglia to that which occurs in the sensorium commune.

15. Prochaska has, therefore, shown that the nervous centres may affect nerves implanted in them in three ways: 1, through mental change, as in voluntary actions; 2, through a physical change originating in the centres themselves; 3, through the reflexion of the change wrought in a sensitive nerve by peripheral stimulation, into a motor nerve: and that nerves may affect centres, 1, so as to excite a feeling in the mind (sensation); and, 2, so as to cause the reflexion of a peripheral change in the afferent sensitive nerve into an adjacent motor nerve, independently of the mind.

16. Prochaska concludes his observations by drawing a careful distinction between those motions which are *animal*, being directed by the mind, and those which are *mechanical* or automatic *(physical)*, of which the mind may or may not take cognizance, but in the production of which it takes no part. In these latter are included the reflex actions.

Such are the conclusions to which Prochaska's observations lead him respecting the nervous system, and in them I confess there appears to me to be a large and an exact view of the phenomena of the nervous system, more comprehensive than the views of Dr. M. Hall respecting an excito-motor power and a special system of excito-motor nerves, and their centre, the true spinal nerves.

In his latest publication, a volume of essays, (1845) Dr. Hall asserts his conviction of the truth of his views, and re-affirms his claims to discovery.

I feel that I owe the reader some apology for this long note. The views of Dr. Hall have been so zealously pressed upon the attention of physiologists and of medical men, that it seemed to me that a work like this ought to contain as full a statement of them as its limits would permit, more especially as I have felt it my duty to express my dissent from them to a very great extent, and to criticize them with much freedom.

Throughout all my remarks it has been my anxious wish to express my opinions regarding Dr. Hall's views as of a pure question of science, omitting all personal considerations. It would have been infinitely more grateful to my feelings to have been able to express my concurrence in these doctrines, (as, indeed, I was at one time much disposed to do,) than to have found myself compelled by regard to truth to refuse assent to his claims to original discovery as well as to his hypothesis, and even to the accuracy of some of his experiments. The cause of science demands that views which are essentially unsound, but which from the urgency with which they continue to be put forward on various occasions and in various shapes, are in danger of being adopted by those who have no time nor opportunity to investigate them closely, should be exhibited in their real shape and purport by means of a careful and searching analysis. Having weighed them in this balance, I must confess that they have been found wanting.

* It would be unjust to a most able physiologist and pleasing writer, Mr. Grainger, not to state that he has contributed much to the distinct enunciation and apt illustration of this hypothesis. See his excellent work on the Spinal Cord. Lond. 1837.

2. A second hypothesis is that which accords with the views of Müller and many other physiologists of the present day, and likewise probably with those of Whytt. It assumes that the fibres of sensation and volition proceed to and from some part or parts of the intracranial nervous mass,—that every nerve-fibre in the body is continued into the brain. Those which are distributed to the trunk and extremities pass along the spinal cord, separating from it with the various roots of the nerves, and in their course within the spine mingling more or less with the vesicular matter of the cord. There are, according to this hypothesis, no other fibres but these, (save the commissural,) and they are sufficient to manifest the physical as well as the mental acts. Nerves of sensation are capable of exciting nerves of motion which are in their vicinity; and they may produce this effect even when the spinal cord has been severed from the brain, for their relation to the grey matter of the cord is such that their state of excitement is readily conveyed to it.

3. According to a third hypothesis, it is assumed that all the spinal and encephalic nerves, of whatever function, are implanted in the grey matter of the segments of the cerebro-spinal centre with which they are severally connected, and *do not pass* beyond them. The several segments of the cerebro-spinal axis are connected with each other through the continuity of the grey matter from one to another, and through the medium of commissural fibres which pass between them. Through these means, motor or sensitive impulses may be propagated from segment to segment; and a stimulus conveyed to any segment from the periphery may either simultaneously affect the brain and cause a sensation, or it may be reflected upon the motor nerves of that segment and stimulate their muscles to contract. Or both these effects may take place at the same moment, as a result of one and the same stimulus. According to this hypothesis, each segment of the cord, so long as it retains its proper commissural connection with the brain (by commissural fibres and continuous grey matter), is part and parcel of the centre of volition as well as of that of sensation, and the mind is as directly associated with each segment of the cord as it is with any portion of the encephalon. Let that commissural connection be dissolved, and the mind will immediately lose its hold upon the cord; but the various segments of that organ may nevertheless still be acted upon by physical impulses, and may still continue to evolve the nervous force in connection with the natural changes which may take place within.

I am not aware that this view of the mechanism of the various actions of the nervous system had been ever distinctly enunciated before it had been stated by Mr. Bowman and myself in our work on the Physiological Anatomy and Physiology of Man, in 1845.* There is nothing, however, in this hypothesis at variance or inconsistent with the views of Prochaska; for this physiologist seems to have held the opinion that the nerves are implanted in the segment of the cerebro-spinal axis into which they sink, and do not pass beyond it.

I shall now examine into the merits of each of these hypotheses, and, first, of the excito-motory hypothesis.

It is unnecessary to repeat the objections already stated (p. 721B) to the use of the term *excito-motory*. I shall only remark that some of these objections are equally opposed to the hypothesis as to its name.

Nevertheless this hypothesis has much to commend it: and not the least argument in its favour is that drawn from the compound nature of spinal nerves, as proved by Bell, in which nerve-fibres of different endowments are bound together in the same sheath. If it be proved (as it has been) that fibres of sensation and of motion may be thus placed in juxtaposition in the same nervous trunk, it seems not an unreasonable conjecture that fibres of other function (*excitors* and their corresponding *motors*) might be enclosed in the same sheath with them.

Both anatomy and experiment, however, unite to prove the existence of sensitive fibres distinct from motor fibres; they are found separate in the roots of the nerves, and combined in the nervous cords: but neither anatomy nor experiment favours the existence of a distinct series of excitor and of corresponding motor nerves. Anatomical research affords not the slightest indication of such a series of nerves. And experiments on the roots of the nerves, where it might reasonably be expected that the excitors would be separated from the motors (following the analogy of the motor and sensitive fibres), are by no means favourable to the existence of such fibres in the roots. The failure of experimenters to excite motion by irritation of the posterior roots of the spinal nerves has been already referred to. A new and extensive series of experiments is much needed to settle this question. I would remark that galvanism should not be used in them, as the results of stimulation by that agent are extremely fallacious, from its liability to extend beyond the parts included between the electrodes.

Other very serious anatomical objections may be urged to this hypothesis. It supposes the existence of two sets of fibres in the spinal cord. Evidence in favour of these is wanting just as much as in favour of those in the roots of the nerves. Many facts favour the conclusion that the fibres which constitute the roots of the nerves of any segment of the cerebro-spinal centre are implanted in the grey matter of that segment, and that none of them are continued beyond that segment up into the brain. They penetrate the spinal cord more or less obliquely, and form their connection with the grey matter a little higher up than the point of penetration; but there is no evidence to show that they assume a completely vertical direction to pass up to the brain.

The form and varying dimensions of the spinal cord in its several regions are opposed to this view. If the sensori-volitional fibres are

* The Physiological Anatomy and Physiology of Man, by R. B. Todd and Wm. Bowman, vol. i. p. 323.

all continued up into the brain, and the (so-called) excito-motor fibres are implanted in the cord, that segment of the cord should be the largest in which the greatest number of these fibres is to be found. Now the great extent of excitor surface in the lower extremities, the magnitude of their muscles, the importance of their movements, and, at the same time, the great developement of reflex actions in them, would lead most reasonably to the expectation that the lumbar segment of the cord to which these nerves belong should exceed considerably in size the cervical segment which gives nerves to the upper extremities, where the excitor surface is of less extent, where the muscles are less powerful, and the reflex actions considerably less conspicuous. Moreover, the lumbar region of the cord would be, if Dr. Hall's views were correct, the centre of those excito-motor acts connected with defæcation, micturition, parturition, &c., of which he speaks so much, and on this account might fairly claim a greater amount of substance. But the fact is, that the lumbar swelling of the cord is smaller than the cervical; and that while it contains, and owes its bulk mainly to, a large quantity of vesicular matter, but a small proportion of fibrous matter is found in it. Moreover, it is impossible to understand the great superiority of size of the lumbar portion over the dorsal segment of the cord, if we are to admit that this latter segment contains in addition to its own fibres (sensori-volitional and excito-motory) the sensori-volitional fibres of the lumbar swelling also, which ought to be very numerous.

It is very generally admitted that the only channel by which the will can influence the spinal cord is through the fibres of the anterior pyramids of the medulla oblongata, the greater number of which decussate each other along the median line. But it is in the highest degree improbable that these fibres, occupying so small a space as they do, should form the aggregate of the volitional fibres (still less of the sensori-volitional fibres) of the trunk and extremities. The whole of these fibres (of *both* sides) collected together would scarcely equal in bulk the anterior portion of *one* of the antero-lateral columns of the spinal cord.

It has been affirmed that much support is given to the excito-motory hypothesis by Dr. Carpenter's and Mr. Newport's supposed demonstration of the two sets of fibres in the Articulata. But these observations are far from deserving the name of *demonstration*. The inferences from them are derived from the *apparent* direction of certain fibres, and not from any actual tracing of them by dissection or by microscopic inspection. The observations, too, have been made with low powers, which are very insufficient for determining the precise disposition of the fibres and their relation to the vesicular matter of the ganglia.

These writers affirm that the longitudinal fibres of the ganglionic chain of Articulata pass up to the brain and constitute the sensori-volitional fibres, whilst other fibres pass in a transverse direction and are implanted in the ganglia. Were this the case, it might reasonably be expected that the brain would be the largest of the ganglia as containing the sum of the sensori-volitional fibres of the whole body. But let any one compare the size of the cerebral ganglia of the scorpion (as figured by Mr. Newport*) with the size of the animal and that of its cord, and it will be evident to him how disproportionately small such a centre is to the number of sensori-volitional fibres which must be distributed over so large a surface and to so many muscles. Anatomy, however, offers no objection to the hypothesis that the roots of the nerves are implanted in the ganglia, and that the longitudinal fibres act as commissures between different segments (adjacent and remote) of the cord.

Neither do Mr. Newport's experiments on the myriapods and other Articulata throw any new light on the question of the existence of two orders of fibres; nor do they add anything to our knowledge beyond the important fact that actions take place in certain Invertebrata after decapitation, which are of the same nature with those which occur in Vertebrata after a similar mutilation. The *mechanism* of these actions has not been at all elucidated by these experiments.

The excito-motory hypothesis is sufficient for the explanation of the movements of decapitated animals, of parts in connection with small segments of the spinal cord, of limbs paralysed to sensation and voluntary motion from diseased brain or spinal cord. But there are two phenomena familiar to those who observe disease with care, which cannot be explained by it; these are the movements which may be excited by mental emotion in limbs paralysed to the influence of the will, and the total paralysis of the sphincter ani, which frequently accompanies diseased brain, whilst at the same time the limbs are only affected to a partial extent or not at all.

Cases occur sometimes in which hemiplegia arises from an apoplectic clot, or other destructive lesion in one hemisphere of the brain. The arm and leg, or either of them, are completely removed from the influence of the will; yet occasionally, as the effect of some sudden emotion, fear, joy, surprise, the paralysed limb is raised involuntarily. Even so slight a cause as yawning (an act of emotional kind) will excite the palsied limb. Every time the patient yawns the arm will be raised involuntarily.

Such phenomena as these receive no adequate explanation from the excito-motory hypothesis. Mental emotions probably affect some part of the brain; if the only communication between the brain and the limbs be by fibres of sensation and volition, it is impossible to understand how the emotional influence could be conveyed to them through a channel which has long been interrupted. If we are to adopt the excito-motory hypothesis, it will be necessary to suppose with Dr. Carpenter the existence of certain emotional fibres to explain the phenomena of this particular case. But it is difficult to admit the existence of three orders

* Phil. Trans. 1844.

of fibres in each muscle, which, to be effective, must have the same relation to the component elements of the muscle. It is impossible to imagine how each order of fibre should comport itself with reference to the other two, so that their actions may not interfere. Nor can any one fail to perceive that the emotional fibres must be infinitely less frequently employed than the others, and in some individuals so seldom called into action as to be greatly exposed to the risk of atrophy for want of use.

Another phenomenon, which this hypothesis fails to explain, is the paralysis of the sphincter ani muscle which accompanies certain lesions of the brain, generally of grave import. Such lesions are almost always accompanied by paralysis, chiefly of the hemiplegic kind, but not necessarily complete. On the contrary, in several such cases distinct reflex actions exist, indicating that, although the brain's influence is withheld from the limbs, that of the cord is not. If, then, the cord be sufficiently free from morbid depression to allow of reflex movements taking place in the inferior limbs, why is the sphincter ani (the actions of which according to Dr. Hall are eminently reflex) so completely paralysed that it offers not the slightest resistance to the introduction of the finger into the anus? So long as the cord is free from lesion and so capable of performing its functions that the lower limbs exhibit reflex movements, the sphincter ani muscle ought not to be paralysed, if the excito-motor hypothesis be true. For, admitting that this muscle has sensori-volitional fibres which are paralysed by the cerebral lesion, it should have excito-motor fibres likewise which ought to enable the muscle to resist the entrance of the finger into the rectum. Such resistance, however, it certainly does not make, for the muscle is completely paralysed in the cases referred to. And it is plain that, according to the excito-motory hypothesis, a cerebral lesion ought not to affect the sphincter ani further than to destroy the control of the will over it, unless the depressing influence of the lesion extend to the whole cord, and in such a case there ought to be complete paralysis of the limbs likewise.

In fine, it cannot be denied that the excito-motor hypothesis takes a narrow and confined view of that power of the nervous centres which it professes to elucidate. As I have before remarked, it limits this power to the excitation of motion, and it confines the exciting agency to nerves which naturally propagate *centrad*, and which only propagate such impressions as may excite movements.

Now it admits of unquestionable proof that impressions on sensitive nerves may, by a process of reflexion, excite other sensitive nerves. Are we to suppose the existence of a special series of fibres for such phenomena? Such a supposition would involve the most palpable contradictions, and is wholly inadmissible.

The second hypothesis, which accords with the views of Müller, is just as competent to explain the phenomena of decapitated animals, and of limbs paralysed to cerebral influence, as that of Dr. Hall. It receives considerable support from the universal concurrence of sensation or mental perception with those normal actions which Dr. Hall would attribute to excito-motory fibres. If it be supposed that these fibres have a certain relation to the vesicular matter of the cord, there are as good grounds for the further supposition that they may continue to be affected by it after the brain has been separated from the cord. This hypothesis, however, is as inadequate as that of excito-motory fibres to explain the influence of emotion on paralysed limbs; and it likewise fails to explain the paralysis of the sphincter, which, under this hypothesis, ought to occur in every case of cerebral disease. The chief objection, however, to this hypothesis is anatomical; for it is far from being proved that the fibres of the spinal nerves are continued upwards through the cord into the brain. For instance, what evidence have we that the fibres of the lumbar region of the cord pass into the brain? The fibres of the anterior pyramids, no doubt, are true cerebro-spinal fibres, because they communicate equally with brain and cord, and distinctly pass from the one to the other; but it cannot be shown that they have any continuity with the fibres of any of the spinal nerves. Much less can it be shown that they contain the fibres which are continued up from, to say the least, the anterior roots of ALL the spinal nerves, which ought to be the case if this hypothesis be correct. The bulk of the pyramids is very much opposed to this view. It is most probable that the pyramids are *cerebro-spinal commissures*. The apparent longitudinal course of the fibres in the spinal cord affords no indication that they pass into the brain, for it is well known that many of the fibres forming the roots of spinal nerves take a very oblique course from their point of separation from the cord to their emergence from the spinal canal; and it is probable that this obliquity is continued in the cord itself, so that their real origin would be much higher up than their apparent one. This great length of oblique course gives to the fibre the appearance of being strictly longitudinal, whereas it may be implanted in the vesicular matter of the cord.

The third hypothesis is more consonant than either of the others with what appears to be the true anatomy of the spinal cord—namely, that each segment has its proper nerves implanted in it, that it is connected with adjacent segments by commissural fibres, and that the whole cord is connected with the cerebrum and cerebellum by commissural fibres; by the anterior pyramids and olivary columns with the former, and by the restiform bodies with the latter.

This hypothesis, the reader will bear in mind, assumes that mental and physical actions are performed through the same fibres—affected by a mental stimulus in the one case, and a physical stimulus in the other—the change produced by the physical stimulus being, in the case of reflex actions, reflected at the centre. The same *afferent* and *efferent* fibres are excited in the one case as in the other, the former acting as *sensitive* or *excitor*, or both; the latter as channels for *voluntary*, *emotional*, or strictly *physical* impulses to motion.

The mechanism of a voluntary action in parts supplied by spinal nerves would be, according to this hypothesis, as follows:—The impulse of volition, excited primarily in the brain, acts at the same time upon the grey matter of the cord (its anterior horn), and through it upon the anterior roots of the nerves implanted in it. This grey matter, in virtue of its association with the brain by means of the anterior pyramids, becomes part and parcel of the organ of the will, and therefore as distinctly amenable to acts of the mind as that portion which is contained within the cranium. If we destroy the commissural connection with the brain through the pyramidal fibres, the spinal cord ceases to take part in mental nervous actions; or, if that connection be only partially destroyed, that portion of the cord which the injured fibres had associated with the brain is no longer influenced by the mind. Again, if the seat of volition in the brain be diseased, the cord or part of it participates in the effects of the disease as far as regards voluntary actions. That it is not too much to ascribe such power to the pyramidal fibres appears reasonable, if we consider how the fibres of the corpus callosum, and perhaps other transverse commissures, so connect the hemispheres and other parts of the brain that the separate divisions of a double organ act harmoniously so as to excite but a single train of thought, or, conversely, that two impressions from one and the same source on a double sentient organ are perceived as single by the mind.

An objection to this explanation will readily be raised—namely, that the excitation of the anterior horn of the grey matter, in the way stated, does not explain the remarkable power which the will has of *limiting* its action to one or two, or a particular class of muscles. To this, however, it may be replied that there can be no reason for denying to the mind the faculty of concentrating its action upon a particular series of the elementary parts of the vesicular matter, or even upon one or more vesicles, if we admit that it can direct its influence to one or more individual fibres, as the advocates of the first and second hypotheses do. If, indeed, we admit the one, we must admit the other; for whether the primary excitation of a fibre take place in the encephalon or in the spinal cord, the part first affected must probably be one or more vesicles of grey matter.

The series of changes which would develope a sensation admits of the following explanation according to this hypothesis:—A stimulus applied to some part of the trunk or extremities is propagated by the sensitive nerves to the *posterior* horn of the grey matter of the spinal cord, and from the junction of this part with the brain, either through the direct continuity of the vesicular matter of the cord with that of the centre of sensation, by the olivary column, or through longitudinal commissural fibres, analogous to or even forming a part of the anterior pyramids, this is simultaneously affected. To this, likewise, it will be objected that the limitation of sensation is not sufficiently explained. But the reply is obvious; the *intensity* and *kind* of sensation depend upon the nature of the primary stimulus at the surface, the *extent* upon the number of fibres there stimulated. Wherever these fibres form their proper organic connection with the vesicular matter, that matter will participate in their change to an extent proportionate to the number of fibres stimulated, and with an intensity commensurate with the force of the primary stimulus. It is not necessary to the developement of sensation that the fibre stimulated should be implanted directly in the brain; if it be connected with this centre through the medium of vesicular matter or through commissural fibres, all the conditions necessary for the developement and propagation of nervous force would appear to be fulfilled. It must not be supposed, however, that in making this statement we mean to assign the spinal cord to be the *seat* of sensation; all we assert is, that the posterior horn of the grey matter, as being the part in which the sensitive roots are implanted, is the seat of physical change excited by the stimulus applied to the sensitive fibres, which change must be *perceived* by the mind before true sensation can be produced. In fine, by the union of the posterior horns of the spinal grey matter with the vesicular matter of the brain, they become a part of the centre of sensation so long as that union is unimpaired.*

This hypothesis offers an explanation of the hitherto unexplained phenomenon of impaired sensation on that side of the body which is opposite to the seat of cerebral lesion. If we regard the anterior pyramids as commissures between the sensitive as well as between the motor portions of the cerebro-spinal centre, it will be obvious that the posterior horns of the spinal grey matter on the right side will be associated with the left centre of sensation, and *vice versâ*.

And we gain, moreover, an explanation of the almost universal association of sensation with reflex or physical nervous actions. The excitor nerves of these actions being the same as the sensitive nerves, the impression conveyed by them is calculated at once to excite motion and sensation. The controlling influence of the will prevents many of the sensitive impressions made through the spinal cord from developing corresponding movements. And this controlling influence is best explained by this hypothesis, for as it admits no other motor nerves connected with the cord but those over which the will can exert an influence, it follows that such mental influence, if more powerful than the physical stimulus which the sentient nerves convey, may prevail over it and neutralize its force. On the other hand, under certain conditions of great physical excitation, (exalted polarity,) physical changes overcome

* In all discussions relative to *sensation* it should be kept in view that true sensation involves a mental act, namely, the *perception* of a physical impression, and of the concomitant physical change in the nervous matter.

mental stimuli, and the mind loses all control; this is the case in poisoning by strychnine, in tetanus, in convulsions.

The difference of structure of the anterior and posterior horns of the vesicular matter of the spinal cord may be appropriately referred to as indicating a difference in functions between these horns. The anterior horns contain large caudate vesicles of a remarkable and peculiar kind, containing a considerable quantity of pigmentary matter; the posterior horns resemble very much in structure the vesicular matter of the cerebral convolutions and of other parts of the cerebrum, and do not contain caudate vesicles, except near the base. Here, then, we find associated with the well-attested difference in the *functions* of the anterior and posterior roots, a striking difference in the *structure* of the anterior and posterior horns of the spinal grey matter in which they are respectively implanted.

We gain from this hypothesis that which neither of the others could supply, namely, an explanation of the influence of emotion on limbs paralysed to volition. Mental emotion excites a change in the brain, probably in that part which forms the upper and posterior portion of the mesocephale: this change is readily propagated to the spinal grey matter through the olivary columns, independently of the pyramidal fibres. The spinal grey matter being excited, the nerves implanted in it are stimulated, and motions are produced closely resembling those which the will can develope.

We have noticed that the will can control reflex or other physical nervous actions. When the influence of the will is suspended, reflex actions may be more easily excited. These facts admit of the most obvious explanation by the hypothesis under examination.

Some reflex actions are imperfectly controllable by the will; such as the contraction of the pupil, and the movement of deglutition at the isthmus faucium. This, however, cannot be cited as at all opposed to the view we are advocating; for there is nothing in this hypothesis repugnant to the idea that certain nerves may be connected in the nervous centres with masses of vesicular matter over which the will usually exercises little or no control, and which, perhaps, may have but a slight connection with the centre of volition through commissural fibres. Still, respecting the two actions above-mentioned, it must be remarked that in deglutition the mental influence is not sufficient by itself: we cannot perfectly contract the fauces, if food or some other physical stimulus be not present; the double stimulus—physical, as of the food, and mental, the will—appears necessary for the perfect performance of this act. In the action of the pupil, the mental stimulus can only be brought to bear on the pupil, by directing it to another muscle at the same time, namely, the internal rectus muscle of the eyeball. When the eyeball is directed toward the nose, the pupil is usually simultaneously contracted.

A double stimulus, mental and physical, appears to be necessary to the perfect developement of many actions. This hypothesis offers a ready explanation of the way in which the two stimuli may combine to promote the same action. The mental stimulus acts directly on the vesicular matter, the physical is propagated to it by sensitive nerves; and thus both acting on the same region of vesicular matter excite the same motor nerves. We have already noticed how this takes place in deglutition at the isthmus faucium. In locomotion there can be no doubt that the double stimulus is in operation: the degree of contraction of the muscles of the lower extremities necessary to maintain the superincumbent weight is obtained by the physical stimulus of pressure against the soles of the feet, where the skin is peculiarly fitted for the reception of such a stimulus; but the movements of the limbs, and the harmonizing association of the muscular actions, are effected by mental influence. The pressure against the soles is felt, however, and the skin of the soles is known to be highly sensitive; and the same nerve-fibres which excite the sensation stimulate the vesicular matter in which the motor nerves are implanted. In many actions of familiar occurrence the voluntary effort is greatly enhanced by the simultaneous application of a physical stimulus to a part of the surface which is supplied with nerves from the same region of the cord. The horseman feels more secure when his legs are in close contact with the horse's flank. We gain a much firmer hold of an object which adapts itself well to the palmar surface of the hand, than of one which, although of no greater bulk, is yet so irregular in surface as not to allow of such intimate contact with the palm. Closure of the eyelids in winking is an action of similar kind, resulting from a physical stimulus, which in the perfect state of the cerebro-spinal centre produces sensation, and excites motion which is at once the result of the physical impression, and of the exercise of volition provoked by the sensation. Every one must be conscious that he exercises considerable control over the movements of his eyelids, and that it requires a great effort to prevent winking for a certain period. At length, however, the physical impression, arising from the contact of air with the conjunctiva, and the diminution of temperature from evaporation on the surface of that membrane, which at first caused but a slight sensation, produces *pain;* the physical stimulus overcomes the mental resistance, and causes contraction of the orbicular muscle. And it may be remarked further, that the closure of the lids by voluntary effort is much more powerful if a stimulus be applied at the same time to the conjunctival surface, than if left solely to the exercise of the will.

In the action just referred to, as well as in all other instances of reflex actions which the will can prevent, no satisfactory explanation of this controlling power of the mind can be given by Dr. Hall's hypothesis. Do the volitional fibres exceed in number the excito-motory? If this were admitted, then we could understand that an excito-motory act might be prevented by substituting a voluntary act for it; but, in the cases in question, the mind prevents action altogether, notwithstanding the exciting influence of the impression. The true explanation seems to be, that the mind can exert upon the vesicular matter a power which can prevent the exercise of that change, or neutralise the change, without which the motor fibres will not be affected by a physical stimulus.

Reflex actions are more manifest in some situations than others: thus, in cases of hemiplegia from diseased brain, they are generally very obvious in the lower extremity, but totally absent in the upper. This, the advocates of the excito-motory theory ascribe to a paucity of excito-motory fibres in the latter limb, and to a larger amount of them in the former. Or, it has been attributed to the greater and more enduring influence of shock upon that segment of the cord from which the nerves of the upper extremities arise, as nearer the seat of lesion, than upon the lumbar segment. But another explanation of this important fact may be offered, which is equally satisfactory, and more accordant with other phenomena. A certain *disposition of the nerves upon the tegumentary surface is as necessary for the developement of reflex actions as of sensations;* and these movements will be more or less easily manifested, according as this organization of the nerves on the surface is more or less perfect.

That disposition of the cutaneous nerves which renders the surface easily excitable by titillation seems most favourable to the developement of these actions. Hence, there is no place where they are more readily excited than in the lower extremities by stimulating the soles of the feet or the intervals between the toes, both of which situations are highly susceptible of titillation. At the isthmus faucium the slightest touch on the surface excites a movement of deglutition; and this touch, at the same time, produces a very peculiar sensation of tickling, quite distinct from that which may be excited at other parts of the pharynx, or mouth. When this part of the mucous membrane is in a state of irritation as an effect of coryza, this tickling sensation is present, and repeated acts of swallowing are provoked.

Two facts may be stated here, which illustrate the position above laid down respecting the necessity of a certain disposition of the nerves *on the tegumental surface*, for the developement of reflex actions. The first is one which has been noticed by Volkmann, and which I have repeatedly observed, namely, that in frogs, and other animals, reflex actions are readily excited by stimulating the feet; but irritating the posterior *roots* of the spinal nerves, which supply those parts, is not sufficient for this purpose. I have already remarked that in numerous experiments upon the posterior roots of the nerves movements have not been excited whilst they have been subjected to irritation, except when galvanism was employed, which, being diffused, affected the cord itself: the recorded statements of most modern experimenters agree in the main with this statement. The second fact is this: in the male frog the developement of a papillary structure on the skin of the thumb seems to have reference to the excitation of the physical power of the cord, to enable the animal to grasp the female without the necessity of a prolonged exercise of volition. Stimulating the fingers will scarcely produce reflex actions, but the slightest touch to the enlarged thumb will cause the animal to assume the attitude of grasping. If the papillæ be shaved off the thumb, its power of exciting these actions is instantly lost.

When the polarity of the cord is greatly excited by strychnine or other substances, or when tetanus exists, all parts of the surface are equally capable of exciting reflex actions. The least touch will cause them, not only in the limb touched, but in all that side of the trunk, or even throughout the whole body. So general is the excitation, that the least impression made on the peripheral extremity of a sensitive nerve in any part of the body is instantly converted into muscular spasm, more or less general. A slight current of air, in tetanus, is sufficient to excite general spasm. Müller remarks that, in such states of the cord, the reflex actions excited by stimulating the nerves themselves are much less than those produced by excitation of the surface.

The readiness with which a physical change, induced in one part of the centre, is propagated to others, whether above or below it, is due no doubt to the vesicular matter. An experiment made by Van Deen illustrates this statement. If, in an animal poisoned by strychnine, the cord be divided in its entire length along the median line, leaving only a slight bridge of grey matter, stimuli applied to any part of the surface will exhibit as extensive reactions as if the cord were entire. It is evident that the only medium of communication between the opposite halves must be the small portion of vesicular matter left undivided.

Impressions conveyed to the cord by the posterior roots of any of its nerves, may be reflected to the corresponding motor nerves, and cause movement, or may extend irregularly along the posterior horns of grey matter and stimulate the nerves implanted in them, and thus give rise to new sensations, which may be referred to other and even distant parts of the body or to new motions.

The hypothesis under consideration affords us an explanation, more satisfactory than any other, of the paralytic state of the sphincter ani in brain disease, already referred to, as well as in that of the spinal cord. This muscle is certainly chiefly under the influence of the will. In ordinary cases of diseased brain, where the lesion is confined to one side, the centre of volition is not sufficiently impaired to affect its influence upon the sphincter. In graver lesions, however, although the will may still continue to exert its control upon one side of the body, it loses its power over the sphincter, which is not excitable by any stimulus. In disease of the spinal cord, there is paralysis of the sphincters if the lesion involve a sufficient portion of the cord's substance, in whatever region of the cord it may exist. Even when the lesion is situate high up in the neck, or in the dorsal region, leaving the lumbar portion perfectly whole, the sphincter will nevertheless be paralysed. In the former instances, the centre of volition in the cranium is diseased; in the latter, the defect consists in the destruction of the communication of the brain with that portion of the cord in which the nerves of the sphincter muscle are implanted.

An examination of the action of the sphincter will show, as has been already noticed, that the anus is kept closed ordinarily by the passive contraction of the muscle itself; but that its active contractions are mainly excited by voluntary influence, allowance being made for some slight action which may be produced by the stimulus of sudden distension, as in other circular muscles. Now, as a stimulus to sentient nerves constitutes no necessary part of any of these actions, it is probable that the motor nerves of the sphincter have little or no connection with the sentient ones; and, consequently, that muscle is not usually excitable to contraction by a stimulus appled to a sentient surface. Hence, whenever the influence of the will upon the lumbar portion of the cord is suspended, this muscle ceases to act, whether a mental or a physical stimulus be exerted.

We have remarked before that all that is shown by Dr. Hall's experiments on the horse and on the turtle is that the spinal cord influenced the sphincter only whilst it was in a state of irritation consequent upon its division. There probably was no real reflex action at all, and the closure of the anus on the application of a stimulus was probably only *apparently* due to that cause, frequent contractions taking place in the muscle in effect of the irritated state of the cord.

On the same principle, animals will exhibit movements of voluntary character for some time after decapitation, the continued irritation of the cord acting as a stimulus. A bird thus treated will fly for some distance, and with considerable energy, and will flap its wings if the cut surface of the cord be irritated. A fly decapitated pursues its course for some way immediately after the removal of the head; and Walckenaer observed a singular fact respecting the *Cerceris ornata*, a wasp which attacks a bee that inhabits holes: " at the moment that the insect was forcing its way into the hole of the bee, Walckenaer decapitated it; notwithstanding which, it continued its motions, and, when turned round, endeavoured to resume its position and enter the hole."* The change in the vesicular matter of the ganglia necessary for the movements of the wasp in pursuit of its prey, had already been excited by a powerful stimulus of volition, which continued even after the removal of the centre from which it had emanated. Actions at first voluntary, which by frequent repetition become habitual and involuntary, are, no doubt, to be accounted for by the persistence of that condition of the vesicular matter which the will at first induced, and to which the frequency of repetition gives a character of permanence. Thus Habit is due, as it were, to the fixation of a certain state of vesicular matter—it is the conversion of a mental into a physical nervous action by frequent repetition.

So similar is the change which a physical stimulus can excite in the grey matter to that produced by the influence of the will, that, as has been often remarked, the actions excited in decapitated animals present a striking resemblance to the ordinary voluntary movements. When a certain portion of the skin is irritated, the animal pushes against the offending substance, as if trying to remove or displace it. If the anus be irritated, both legs are excited to action. It may also be observed, that the same motions follow the same irritations of the skin. If, in a frog, the seat of irritation be on the right side, the corresponding hind-foot will be raised, as if to remove the irritating cause. The exact resemblance of these to voluntary movements seems to admit of being explained only on the supposition that the same fibres are employed in the execution of both.

It must be kept in view, that, while this hypothesis rejects the class of sensori-volitional fibres which are supposed to pass with the spinal nerves along the cord into the brain, it admits the existence of only three orders of fibres implanted in the various segments of the cord, viz. those at once sensitive and excitor; those at once for voluntary and involuntary motion; and commissural fibres; of which the former only contribute to form the nerves. It must not be supposed, however, that it is intended by this hypothesis to assume that the intervention of *sensation* (*i.e.* the perception of an impression by the mind) is *necessary* for the production of those muscular actions which are excited by stimulation of the surface. No more is affirmed than that the same stimulus to the sensitive nerve which can and does excite a sensation, may *simultaneously*, but *independently*, cause a change in the vesicular matter which shall stimulate the motor nerves; and that this change is of the same kind as that which the will may excite, and affects the same motor nerves.

Lastly, this hypothesis involves the enunciation of a highly important proposition with reference to nervous centres. It is this: that all the centres which are connected to the brain by commissural fibres, are thereby submitted to, and brought into connection with, the mind, to an extent proportionate to the number of connecting fibres, so that voluntary impulses act upon them as part and parcel of the centre of volition; and sensitive impressions, in affecting them, affect the mind simultaneously.

In voluntary actions, then, it may be stated that, while the brain is the part primarily affected, the mental impulse is also directed to that portion of the cord upon which the required action depends.

In the developement of sensation the stimulus affects the posterior horns of the grey matter of the cord, which, from its commissural connection with the brain, is in reality a part of the sensorium. When the power of mental

* Quoted in Müller's Physiology, by Baly, vol. i. p. 787*, 2nd ed.

interference is removed, or kept under controul, physical actions develope themselves; being effected through the same nerves as those which volition influences or which sensitive impressions affect. The latter are, in such instances, the excitors of the former, no doubt through the vesicular matter in which they are implanted. These actions become most manifest when the connection of the brain with the spinal cord has been severed; and they occur in the most marked way in those situations where the cutaneous nerves are so organized as readily to respond to the application of a stimulus applied to the surface, or they become universal when the cord is in a state of general excitement.

The movements in locomotion and the maintenance of the various attitudes are effected through the ordinary channels of the physical and volitional actions; and the posterior columns of the cord, by their influence on the vesicular matter of the segments in which the nerves are implanted, co-ordinate and harmonize the complicated muscular actions of the limbs and the trunk under the controul of that portion of the encephalon which probably is devoted to that purpose. This power of coordination is probably mental, and intimately connected with the muscular sense.

FUNCTIONS OF THE ENCEPHALON. — It will be convenient first to examine the functions of those parts of the encephalon which in structure most nearly resemble the spinal cord.

Functions of the medulla oblongata, mesocephale, corpora striata, and optic thalami.— The medulla oblongata most nearly resembles the cord in form and structure, at the same time that it exhibits most marked and important differences from it. Its subdivisions form connections superiorly with other parts of the brain, namely, the mesocephale, corpora striata, and optic thalami. These connections are so intimate, that, however convenient it may be to the descriptive anatomist to describe these parts each by itself, it is impossible, in examining into their functions, to separate them completely. The functions of one part are so readily affected by a change in any or all of the others, that the effects of experiments are not limited only to the part operated upon, but affect or are affected by the rest. Thus, the olivary columns, which form the central and most essential part of the medulla oblongata, extend upwards through the mesocephale to the optic thalami; and the anterior pyramids form an intimate connection not only with the vesicular matter of the mesocephale, but, to a great extent, with that of the corpora striata. All these parts taken together, with the quadrigeminal tubercles, will be found to be the centre of the principal mental nervous actions, and of certain physical actions which are very essential to the integrity of the economy.

The office of the nerves which arise from this segment of the encephalon throws light upon its function. These nerves are partly destined for respiration, partly for deglutition, and partly also for acts of volition and sensation.

Destruction of the medulla oblongata is followed by the immediate cessation of the phenomena of respiration; and this takes place whether it be simply divided, or completely removed. When an animal is pithed, he falls down apparently senseless, and exhibiting only such convulsive movements as may be due to the irritation of the medulla by the section, or such reflex actions as may be excited by the application of a stimulus to some part of the trunk.

If, in an animal which breathes without a diaphragm, as in a bird or reptile, the spinal cord be gradually removed in successive portions, proceeding from below, up to within a short distance of the medulla oblongata, loss of motor and sensitive power takes place successively in the segments of the body with which the removed portions of the cord were connected. But the animal still retains its power of perceiving impressions made on those parts of the body which preserve their nervous connection with the medulla oblongata, and continues to exercise voluntary control over the movements of those parts. The movements of respiration go on, and deglutition is performed. The higher senses are unimpaired.*

These phenomena are sometimes observed in man—in such cases as that alluded to in a former page; where, from injury to the spinal cord in the neck, below the origin of the phrenic nerve, the patient appears as a living head with a dead trunk. The sensibility and motor power of the head are perfect; respiration goes on partially, and deglutition can be readily performed. The senses and the intellectual faculties remain for a time unimpaired.

Irritation of any part of the medulla oblongata excites convulsive movements in muscular parts which receive nerves from it, and, through the spinal cord, in the muscles of the trunk. Spasm of the glottis, difficulty of deglutition, irregular acts of breathing, result from irritation of the medulla oblongata; and, if the excitement be propagated to the cord, convulsions will become more or less general.

If a lesion affect one half of the medulla oblongata, does it produce convulsions or paralysis on the opposite side of the body? This question may be certainly answered in the affirmative, when the seat of the lesion is in the continuations of the columns of the medulla oblongata above the posterior margin of the pons. It is not so easily solved, however, when the disease is situate below the pons. The results of experiment on this subject are contradictory, owing probably to the extreme difficulty of limiting the injury inflicted to a portion of the medulla on one side; and those of Flourens are of no value for the decision of this question, as it appears that he injured chiefly the restiform bodies. Anatomy suggests that a lesion limited to either anterior pyramid would affect the *opposite* side of the trunk, for it is known that such an effect follows disease of the continuation of it in the mesocephale or crus cerebri; and that lesion limited to the posterior half of

* Flourens, p. 179.

the medulla on either side would affect the *same* side of the body, no decussation existing between the fibres of opposite restiform or posterior pyramidal bodies. The irritating or depressing influence of the lesion would probably be extended to the spinal grey matter of the same side.

That the medulla oblongata is the channel through which the operations of the brain are associated in voluntary actions with the spinal cord, is shewn by the fact that paralysis of all the muscles of the trunk follows the separation of the latter organ from the former. It seems not improbable that the centre of volition is connected with one of the gangliform bodies in which the columns of the medulla oblongata terminate above (the corpora striata), so that the column connected with each corpus striatum (the anterior pyramid) is well placed for conveying voluntary impulses downwards. When the cerebral hemispheres have been removed, as in Flourens' and in Magendie's experiments, the bird is thrown into a deep sleep, a state of stupefaction, and insensibility to surrounding objects. But as he can maintain his attitude, stand, walk when first propelled, fly if thrown into the air, it may be inferred that some degree at least of mental or volitional effort remains. Some of the animal's movements have the appearance of the exercise of will, although, doubtless, many of them are in a great degree excited by physical stimuli. I may instance, in particular, what I have noticed in my own repetition of Flourens' experiments, a peculiar movement of the head, as if the bird were trying to shake off some object which irritated the head, and a frequent opening and shutting the bill, with movements of deglutition. Hence there seems reason to believe that the will may be exercised independently of the cerebral convolutions and their fibres, and that, under all circumstances, it exerts a primary influence upon either or both of these gangliform bodies, more vigorous when aided and guided by the power of the cerebral hemispheres. The frequent paralysis of motion apart from sensation, when the upward continuations of the pyramidal fibres in the corpora striata are diseased, renders it extremely probable that these fibres are the media of connection between the brain and cord in voluntary actions.

The medulla oblongata is also the medium for the transmission of sensitive impressions from all the regions of the head, trunk, and extremities; and from its olivary columns at their upper and posterior part in the mesocephale being, as it were, the concourse of all the nerves of pure sense, it seems fair to assign these parts as the prime seat of those central impressions which are necessary for sensation. The reception of these impressions by the cerebral hemispheres is the stage immediately associated with mental perception. Perfect sensation, therefore, cannot take place without cerebral hemispheres. In a sensation excited in parts supplied by spinal nerves, the first central change is probably in the posterior horn of the vesicular matter of the cord; and the olivary column of the medulla oblongata is simultaneously affected, from its connection with the cord. The change in this latter part is then propagated to the cerebral hemispheres.

Thus much is suggested by anatomy, as regards the share which the medulla oblongata takes in the mechanism of sensitive impressions. Experiment affords us no aid in this intricate and difficult subject; neither does pathological anatomy: for the parts are so closely associated with each other, that any morbid state of one readily involves the others, so that it is almost impossible to find a morbid state of the parts devoted to sensation, apart from an affection of those more immediately concerned in motion.

The function of the restiform bodies is probably associated with that of the hemispheres of the cerebellum, and of the posterior columns of the spinal cord.

The experiments of Le Gallois and Flourens make it certain that the medulla oblongata is the centre of respiratory movements. The latter physiologist assigns as the "primum movens" of these acts all that portion of the medulla which extends from the filaments of origin of the vagus nerve to the tubercula quadrigemina, the former only inclusive. Destruction of this portion, in whole or in part, invariably impairs or destroys the respiratory actions, and a morbid state of it gives rise to irregular or excited movements of respiration. Sighing, yawning, coughing, are probably connected with excitation of this centre, either direct, or propagated to it from some sentient surface. It seems not improbable that a portion of the spinal cord as low down as the spinal accessory nerve goes, is associated with this centre in the respiratory movements.

This portion of the encephalon is also the centre of action in the movements of deglutition, through fibres of the glosso-pharyngeal and vagi nerves. A morbid state of it occasions difficulty, or even paralysis, of deglutition. Animals deprived of the cerebral hemispheres and cerebellum will preserve the power of swallowing food introduced within the grasp of the fauces, so long as the medulla oblongata continues uninjured. In fœtuses born without cerebral hemispheres, those actions are present which depend on the spinal cord and medulla oblongata; all the movements of respiration and deglutition are performed as well as in the perfect fœtus. Mr. Grainger's experiments shew that puppies deprived of the hemispheres of the brain can perform the movements of suction with considerable vigour, when the finger is introduced into the mouth;* and the remarkable fact of the adhesion of the fœtus of the kangaroo to the nipple within the pouch, no less than its respiratory movements, must, as this author remarks, be regarded as a most interesting display of the physical power of the medulla oblongata, while the rest of the brain is as yet undeveloped.

The actions of respiration and pharyngeal

* Loc. cit. pp. 80-1.

deglutition are, to a great extent, of the physical kind, being excited by impressions propagated from the periphery. In those of respiration, the ordinary exciting cause is probably, as Dr. Hall suggested, due to the chemical changes in the respired air which are effected in the lungs. These movements may be, to a certain extent, controlled by the will; but every one is conscious, from his own sensations, that after a time the physical stimulus is capable of conquering the restraining influence of the mind; a striking example of a mental stimulus giving way to a physical one, and illustrative of the doctrine that the same fibres are affected by both stimuli. The excitation of the medulla oblongata in respiration does not, however, depend solely upon the pulmonary nerves. Those of the skin are capable of exciting it, either directly as the fifth pair, or through the spinal cord, as is proved by the inspirations which are instantly excited by suddenly dashing cold water on the face or trunk.

In deglutition, the exciting cause is the stimulus of contact applied to the mucous membrane of the fauces. So highly sensitive is the mucous membrane in this situation, that the slightest touch of it with a feather is sufficient to produce contraction of the muscles of deglutition, which the will is scarcely able to control. Without this stimulus, it is doubtful whether these muscles would obey the will alone, and it seems probable that this part of the act of deglutition must be regarded as one of those actions referred to at a former page, which require a double stimulus, both mental and physical, for their full performance.

The medulla oblongata and its continuations in the mesocephale appear to be the centre of those actions which are influenced by emotion. The common excitement of movements of deglutition or respiration, or of sensations referred to the throat, under the influence of emotion, evidently points to this part of the cerebro-spinal centre as being very prone to obey such impulses; and as the nerves of pure sense, especially the optic and auditory, are very commonly the channels of sensitive impressions well calculated to arouse the feelings, it seems highly probable that the centre of such actions should be contiguous to the origin of these nerves. This office may be assigned to that region of the mesocephale which is in the vicinity of the quadrigeminal tubercles. It is not a little remarkable that the nerves which arise from this and the neighbouring parts are very readily influenced by emotions. Thus, the third and fourth pairs of nerves regulate the principal movements of the eyeballs, those especially which most quickly betray emotional excitement; and the portio dura of the seventh pair, the motor nerve of the face, is the medium through which changes of the countenance are effected. It may be added, that the centre of emotional actions ought to be so situated that it might readily communicate with the centres of all the voluntary actions of the body, and with the immediate seat of the intellectual operations, as well as with the nerves of pure sense; and no part possesses these relations so completely as that now under examination.

In those diseases which mental emotion is apt to give rise to, many of the symptoms are referable to affection of the medulla oblongata. In hysteria, the globus, or peculiar sense of suffocation or constriction about the fauces; in chorea, the difficulty of deglutition, the peculiar movement of the tongue, the excited state of the countenance, the difficulty of articulation, may be attributed to the exalted polarity of the centre of emotional actions. In hydrophobia this part is probably always affected, and frequently so in tetanus.

Certain gangliform bodies are connected with the upward continuations of the medulla oblongata, both in the brain and in the mesocephale, which doubtless have proper functions. These are the corpora striata, optic thalami, and quadrigeminal bodies.

Corpora striata.—The anatomy of the corpora striata and optic thalami, while it denotes a very intimate union between them, also shows so manifest a difference in their structural characters, that it cannot be doubted that they perform essentially different functions. In the corpora striata the fibrous matter is arranged in distinct fascicles of various sizes, many, if not all of which, form a special connection with its vesicular matter. In the optic thalami, on the other hand, the fibrous matter forms a very intricate interlacement, which is equally complicated at every part. Innumerable fibres pass from one to the other, and both are connected to the hemispheres by extensive radiations of fibrous matter. The corpora striata, however, are connected chiefly, if not solely, with the inferior fibrous layer of each crus cerebri; whilst the optic thalami are continuous with the superior part of each crus, which is situate above the locus niger.

It will be observed, then, that while these bodies possess, as a principal character in common, an extensive connection with the convoluted surface of the brain, they are, in the most marked way, connected inferiorly with separate and distinct portions of the medulla oblongata; the corpora striata with the inferior fibrous planes of the crura cerebri and their continuations, the anterior pyramids; and the optic thalami with the olivary columns, the central and probably fundamental portions of the medulla oblongata. This anatomical fact must be taken as an additional indication that these gangliform bodies perform separate functions.

Now, it may be inferred, from their connections with nerves chiefly of a sensitive kind, that the olivary columns, and the optic thalami, which are continuous with them, are chiefly concerned in the reception of sensitive impressions, which may principally have reference merely to informing the mind (so to speak), or partly to the excitation of motion, as in deglutition, respiration, &c. The posterior horns of the grey matter of the cord, either by their direct continuity with the olivary columns, or their union with these columns through commissural fibres, become part and parcel of a great centre of sensation, whether for mental or physical actions.

The pyramidal bodies evidently connect the grey matter of the cord (its anterior horns?) with the corpora striata; and not only these, but also the intervening masses of vesicular matter, such as the locus niger, and the vesicular matter of the pons, and of the olivary columns; and, supposing the corpora striata to be centres of volition in intimate connection with the convoluted surface of the brain by their numerous radiations, all these several parts are linked together for the common purposes of volition, and constitute a great centre of voluntary actions, amenable to the influence of the will at every point.

It has been pretty generally admitted by anatomists, that both the corpora striata and the anterior pyramids are concerned in voluntary movements. The motor tracts of Bell were regarded by that physiologist as passing upwards from the anterior columns of the cord to the corpora striata, and, after traversing those bodies, as diverging into the fibrous matter of the hemispheres; and the fact of the origin of certain motor nerves, in connection with those fibres, was considered to be very favourable to this view. The decussation of the pyramids, likewise, so illustrative of the cross influence of the brain in lesions sufficient to produce paralysis, has been looked upon as an additional indication of the motor influence of these parts.

The invariable occurrence of paralysis as the result of lesion, even of slight amount, in the corpora striata, must be regarded as a fact of strong import in reference to the motor functions of these bodies.

Nor is this fact at all incompatible with the statements made by all experimenters, that simple section of the corpus striatum does not occasion either marked paralysis or convulsion; and that in cutting away the different segments of the brain, beginning with the hemispheres, convulsions are not excited until the region of the mesocephale is involved. The influence of the corpora striata is not upon the nerves *directly*, but upon the segments of the medulla oblongata or of the spinal cord, and, through them, upon the nerves which arise from them. Were the nerve-fibres continued up into the corpora striata, according to an opinion which has been long prevalent, there would be no good reason for supposing that they should lose in the brain that excitability to physical stimuli which they are known to possess in the spinal cord, and at their peripheral distribution.

The latest experiments of this kind, which are those of Longet and Lafargue, agree in the following result, which is not at variance with that obtained by Flourens. The animals remain immoveable after the removal of the corpora striata, whether those bodies have been removed alone or in conjunction with the hemispheres; nor do they show any disposition to move, unless strongly excited by some external stimulus. None of these observers had noticed the irresistible tendency to rapid propulsion, which was described by Magendie. Removal of the corpus striatum of one side caused weakness of the opposite side.

In order to form a due estimate of these experiments, it must be borne in mind, that the effects of simple excision of either corpus striatum would be very different from those of disease of it. The depressing effects of the latter would be absent, at least, until some alteration in the process of nutrition had been set up in the mutilated parts. Simple excision of the centre of volition, and inflammatory disease of its substance, or an apoplectic clot, must produce essentially different effects;—the one simply cuts off the influence of the will, the other affects the vital action, and, consequently, the vital power of the cenrre, and of the commissural fibres connected with it.

Judging from structure only, it might be conjectured that the *locus niger*, that remarkable mass of vesicular matter which separates the anterior and posterior planes of each crus cerebri, exerts a motor influence. It resembles in structure the anterior horns of the grey matter of the cord, and contains numerous large caudate vesicles with very abundant pigment, and is the immediate centre of implantation of a very important motor nerve, the third pair, which regulates the movements of nearly all the muscles of the eyeball.

Optic thalami.—The same line of argument which leads us to view the corpora striata as the more essential parts of the nervous apparatus which controul direct voluntary movements, suggests that the optic thalami may be viewed as the principal foci of sensibility, without which the mind could not perceive the physical change resulting from a sensitive impression.

The principal anatomical fact which favours this conclusion is the connection of all the nerves of pure sense, more or less directly, with the optic thalami or with the olivary columns. The olfactory processes, which apparently have no connection with them, form, no doubt, through the fornix, such an union with them, as readily to bring them within the influence of the olfactory nerves.

According to this sense of its office we must regard the optic thalami as the upper and chief portions of an extended centre, of which the lower part is formed by the olivary columns, which we have already referred to as taking part in the mechanism of sensation. The continuity of the olivary columns with the optic thalami justifies this view: nor is it invalidated by the fact, that some of the nerves which arise from the medulla oblongata are motor in function; for Stilling's researches render it probable that these fibres have their origin in special accumulations of vesicular matter, which contain caudate vesicles of the same kind as those found in the anterior horns of the grey matter of the cord.

The results which experiments have yielded add little that is positive to our knowledge of the functions of these bodies. Flourens found that neither pricking nor cutting away the optic thalami by successive slices occasioned any muscular agitation, nor did it even induce contraction of the pupils. Longet found that removal of one optic thalamus in the rabbit was followed by paralysis on the opposite side of the body. It appears, however, that this was done after the removal of the hemisphere and corpus striatum, whereby the experiment was so complicated as to invalidate any conclusion that might be drawn from it respecting the function of the thalamus. Indeed, vivisections upon so complex an organ as the brain are ill-calculated to lead to useful or satisfactory results; but one does not hesitate to refer to such as have been made, because they afford a certain amount of negative information, imperfect though it be.

Nothing definitive respecting the proper office of the thalami can be obtained from pathological anatomy. Extensive disease of these bodies is attended with the same phenomena during life, as lesion of similar kind in the corpora striata. Hemiplegic paralysis accompanies both; nor does it appear that sensation is more impaired when the thalamus is diseased, than when the corpus striatum is affected.

There is nothing in the phenomena attendant on morbid states of the thalami which can be fairly regarded as opposed to the conclusion which their anatomical relations indicate, namely, that they form a principal part of the centre of sensation. The intimate connection between the striated bodies and the thalami sufficiently explains the paralysis of motion which follows disease of the latter; whilst, as the thalami do not constitute the *whole centre* of sensation, but only a part thereof, it cannot be expected that lesion of this *part* would destroy sensation, so long as the remainder of the centre on the same side, as well as that of the opposite side, retain their integrity. Complete paralysis of sensation on one side is very rare in diseased brain: a slight impairment of it frequently exists in the early periods of cerebral lesion, apparently as an effect of shock; for it quickly subsides, although the motor power may never return.

According to the views above expressed, the corpora striata and optic thalami bear to each other a relation analogous to that of the anterior to the posterior horn of the spinal grey matter. The corpora striata and anterior horns are centres of motion; the optic thalami and posterior horns, centres of sensation. The anterior pyramids connect the former; the olivary columns, and perhaps some fibres of the anterior pyramids, the latter. The olivary columns, however, are in great part continuations of the thalami on the one hand, and of the grey matter of the cord on the other; and contain abundance of vesicular matter, in which nerves are implanted.

And it must be admitted that the intimate connection of sensation and motion, whereby sensation becomes a frequent excitor of motion,—and voluntary motion is always, in a state of health, attended with sensation,—would *à priori* lead us to look for the respective centres of these two great faculties, not only in juxta-position, but in union at least as intimate as that which exists between the corpus striatum and optic thalamus, or between the anterior and the posterior horns of the spinal grey matter.

Saucerotte, Foville, Pinel Grandchamps, and others, advanced the opinion that the corpora striata and the fibrous substance of the anterior lobes of the brain had a special influence upon the motions of the lower extremities, and that the optic thalami and the fibrous substance of the middle and posterior part of the brain presided over the movements of the upper extremities. We find, however, but little to favour this theory either in the results of experiments, in pathological observation, or the anatomy of the parts. Longet states, that, in his experiments upon the optic thalami, the paralysis affected equally the anterior and the posterior extremities. Andral analysed seventy-five cases of cerebral lesion limited to the corpus striatum or optic thalamus. In twenty-three of these cases, the paralysis was confined to the upper extremity: of these, *eleven* were affected with lesion of the corpus striatum or of the anterior lobe; *ten* with lesion of the posterior lobe, or of the optic thalamus; and *two* with lesion of the middle lobe.* Hence it is plain that a diseased state of the corpus striatum is as apt to induce paralysis of the upper extremity as lesion of the thalamus; and we are forced to conclude, that pathological anatomy is not competent to decide the question. Lastly, the anatomy of these two bodies renders it highly improbable that they perform a function so similar, as that of directing the movements of particular limbs. The great size of the optic thalamus, its multitude of fibrous radiations, its extensive connections both in the medulla oblongata and in the hemispheres by means of commissural fibres, the marked difference of its structure from that of the corpus striatum, its connection more with the posterior horns of the spinal grey matter than with the anterior ones, and its intimate relation to nerves of sensation, are sufficient anatomical facts to warrant the opinion that the thalami must perform a function which, although it may be subservient to, or associated with, that of the striated bodies, is yet entirely dissimilar in kind.

It has been supposed that the corpora striata are special centres or ganglia to the olfactory nerves, and to the sense of smell. But such a supposition is altogether superfluous, inasmuch as a very distinct and obvious centre to these nerves exists in the olfactory process or lobe, miscalled *nerve* by descriptive anatomists. The small olfactory nerves are implanted in the anterior extremity or bulb of this process, which is provided with all the structural characters of a nervous centre, and contains a ventricle. This lobe, moreover, is always developed in the direct ratio of the size and number of the olfactory nerves, and of the developement of the sense of smell; and in the Cetacea, a class in which the olfactory nerves and process either do not exist at all, or are so imperfectly developed as to have

* Clin. Med. t. v.

escaped the notice of some of the ablest anatomists, the corpora striata are of good size proportionally to that of the entire brain.

Corpora quadrigemina.—The marked connection of these gangliform bodies with the optic nerves plainly indicates that they bear some special relation to those nerves, and to the sense of vision; and this indication becomes more certain when we learn, from comparative anatomy, that in all vertebrate tribes in which the encephalon is developed, special lobes exist, bearing a similar relation to the optic nerves. When the optic nerves are large, these lobes are large; and in the Pleuronecta, in which the eyes are of unequal size, Gottsche states that the optic lobes are unequal, and are related in size to each other, as the eyeballs are. Still, as Serres has remarked, the quadrigeminal tubercles probably perform some other office besides that which refers to vision; inasmuch as the absence, or extremely diminutive size, of the optic nerves in some animals (the mole for instance) does not materially affect that of these bodies.*

Flourens found that destruction of either of these tubercles on one side was followed by loss of sight of the opposite side, and consequently that the removal of both deprived the animal altogether of the power of vision, but did not affect its locomotive or intellectual powers, nor its sensibility, except to light. In these experiments the action of the iris was not impaired if the tubercles were only partially removed; as long as any portion of the roots of the optic nerves remained uninjured, the iris continued to respond to the stimulus of light, but the total removal of the tubercles paralysed the irides. If the lobes of the brain and cerebellum were removed, leaving the tubercles untouched, the irides would continue to contract. These experiments leave no room to doubt that the optic tubercles are the encephalic recipients of the impressions necessary to vision, which doubtless are simultaneously felt by means of the optic thalami; and that they are the centres of those movements of the iris which contribute largely not only to protect the retina, but likewise to increase the perfection of vision. The optic nerve is at once the nerve of vision, and the excitor of motor impulses which are conveyed to the iris by the third nerve, which takes its origin very near to the optic tubercles. It is interesting to add, that irritation of an optic tubercle on one side causes contraction of both irides:—this is quite in accordance with the well-established fact, that, if light be admitted to one eye so as to cause contraction of its pupil, the other pupil will contract at the same time. So simultaneous is the action of the two centres; so rapid must be the transmission of the stimulus from one side to the other.

When the injuries inflicted on these tubercles were deep, more or less general convulsive movements were produced; if one tubercle were injured, the opposite side only was so affected. These convulsions were due to the lesion of the central parts of the medulla oblongata, with which the optic tubercles are intimately connected. A remarkable vertiginous movement was likewise caused, the animal turning to the side from which the tubercle had been removed. It does not appear that this rotation could be attributed to any special influence of the medulla oblongata, but rather to a state of vertigo induced by the partial destruction of vision; for Flourens found that the same effects could be produced in pigeons by blindfolding one eye. The movements, however, were not so rapid, nor did they continue so long. And Longet saw the same movements in pigeons in which he had evacuated the humours of one eye.*

It may be remarked, that deep injuries to the quadrigeminal tubercles are very likely to affect the only commissural connection between the cerebrum and cerebellum (*processus cerebelli ad testes*), the integrity of which must doubtless be essentially necessary to ensure harmony of action between these two great nervous centres.

There are many instances on record in which blindness was coincident with pathological alteration of structure in one or both quadrigeminal tubercles. In some of the cases where the lesion extended to parts seated beneath the tubercles, disturbed movements were observed, as in the experiments above related.

We are ignorant of the object of the extensive connections of the optic tracts with the tuber cinereum, the crura cerebri, and the corpora geniculata; but these points are highly worthy of future inquiry, especially with reference to the office of these last-named bodies, which is at present involved in much obscurity. Many of the fibres of the optic tracts are undoubtedly commissural between the corresponding points of opposite sides, and exist when those which form the optic nerves are deficient.

We see, then, in the quadrigeminal tubercles, centres, which, whatever other functions they may perform, have a sufficiently obvious relation to the optic nerves, the eye, and the sense of vision. This is clearly indicated by anatomical facts, especially by those of comparative anatomy, by the results of experiment, and by the phenomena of disease. These bodies may, therefore, be justly reckoned as special ganglia of vision; and we are led to seek for similar centres in connection with the other senses. The olfactory processes seem very probably to perform a similar office in reference to the sense of smell. Their structure, their relation to the olfactory nerves, and their direct proportion of bulk to that of these nerves, and to the developement of the olfactory apparatus, place this question beyond all doubt. It is not so easy to determine the special ganglia of hearing; but the olivary *bodies*, or the small lobules connected with the crura cerebelli called by Reil *the flocks*, may be referred to as bearing a sufficient close anatomical relation to the

* Vid. OPTIC NERVES.

* Flourens' experiments have been amply confirmed by those of Hertwig and Longet.

auditory nerve to justify our regarding either of them as well calculated to perform this function. And, with respect to touch, the ganglia on the posterior roots of the spinal and the fifth nerves may perhaps be considered in the same light; for this sense being diffused so universally, in various degrees, over the whole surface of the body, and being seated in a great number of different nerves, would need ganglia in connection with all those nerves which are adapted to the reception of tactile impressions. The analogous sense of taste has its ganglia in those of the glosso-pharyngeal and the fifth.*

The upper and posterior part of the mesocephale has already been referred to, as being most probably that part of the brain which is most directly influenced by emotional excitement. Dr. Carpenter appears to localize the seat of emotional influence more specially in the corpora quadrigemina, and refers to certain fibres, which he considers terminate in those bodies, as channels of emotional impulses. Although I am compelled to differ from this able writer in this limitation of the centre of emotion (so to speak), and am far from admitting the existence of a distinct series of fibres for emotional acts, I nevertheless think that the arguments he advances are most applicable to that view which refers the influence of emotion to the grey matter of this entire region, which is brought into connection with the spinal cord by the fibres of the anterior pyramids, as well as probably through the continuity of the olivary columns and the posterior horns of the spinal grey matter.

Every one has experienced in his own person how the emotions of the mind, whether excited by a passing thought, or through the external senses, may occasion not only involuntary movements, but subjective sensations. The thrill which is felt throughout the entire frame when a feeling of horror or of joy is excited, or the involuntary shudder which the idea of imminent danger or of some serious hazard gives rise to, are phenomena of sensation and motion excited by emotion. The nerves which take their origin from the medulla oblongata, mesocephale, or crura cerebri, are especially apt to be affected by emotions. The choking sensation which accompanies grief is entirely referable to the pharyngeal branches of the glosso-pharyngeal and vagi nerves, which come from the olivary columns. The flow of tears which the sudden occurrence of joy or sorrow is apt to induce may be attributed to the influence of the fifth nerve, which is also implanted in the olivary columns, upon the lachrymal gland; or of the fourth nerve, which anastomoses with the lachrymal branch of the fifth. The more violent expressions of grief, sobbing, crying, denote an excited state of the whole centre of emotion, involving all the nerves which have connection with it, the portio dura, the fifth, the vagus, and glosso-pharyngeal; and even the respiratory nerves, which take their origin from the spinal cord, as the phrenic, spinal accessory, &c. And laughter, "holding both his sides," causes an analogous excitation of the same parts of the central organ and of the same nerves. The very different effect produced by the excitement of the same parts must be attributed to the different nature of the mental stimulus.

As the passing thought—the change wrought during the exercise of the intellect—may excite the centre of emotion, so this latter may exert its influence upon the general tenor of the mind, and give to all our thoughts the tinge of mirth or sadness, of hope or despondency, as one or the other may prevail. We say of one man, that he is constitutionally morose; of a second, that he is naturally gay and mirthful; and of a third, that he is a nervous man, and that he is never likely to be otherwise. One man allows his feelings to hurry him on to actions which his intellect condemns; whilst another has no difficulty in keeping all his feelings in entire subjection to his judgment. "Of two individuals with differently constituted minds," remarks Dr. Carpenter, "one shall judge of everything through the medium of a gloomy morose temper, which, like a darkened glass, represents to his judgment the whole world in league to injure him; and all his determinations, being based upon this erroneous view, exhibit the indications of it in his actions, which are themselves, nevertheless, of an entirely voluntary character. On the other hand, a person of a cheerful, benevolent disposition, looks at the world around as through a Claude-Lorraine glass, seeing everything in its brightest and sunniest aspect, and, with intellectual faculties precisely similar to those of the former individual, he will come to opposite conclusions: because the materials which form the basis of his judgment are submitted to it in a very different form."* Such examples abundantly illustrate the important share which the emotions take in the formation and developement of character, and how all things presented to the mind through the senses may take their hue from the prevailing state of the feelings. If a certain part of the brain be associated with emotion, it is plain that that part must be in intimate connection with the seat of change in the operations of the intellect, in order that each may affect the other; that the former may prompt the latter, or the latter excite or hold in check the former. And this association of the emotions with a certain portion of the brain explains the influence of natural temperament, and of varying states of the physical health, upon the moral and intellectual condition of individuals. We may gather from it how necessary it is to a well-regulated mind that we should attend not to mental culture only,

* It may be urged against this conjecture respecting the functions of the ganglia of the spinal nerves and the fifth, that the analogy between these bodies and the quadrigeminal tubercles is incomplete, inasmuch as the optic nerves are probably *implanted* in the latter, but the nerves of touch merely *pass through* the former. But, in truth, we know so little of the positive relation of the nerves in question to the ganglia, that no argument, either for or against the above view, can rest upon such imperfect information.

* Carpenter's Physiology.

but to the vigour and health of the body also; that to ensure the full developement of the *mens sana* we must secure the possession of the *corpus sanum*.

Certain diseases are evidently associated with disturbed or excited states of emotion. In such cases, the nerves most affected are those connected with the mesocephale and medulla oblongata, denoting an excited state of these portions of the encephalon. Of these diseases the most remarkable are *hysteria* and *chorea;* both of which may be induced either by a cause acting primarily upon the mind, or by functional disturbance of the body, as deranged assimilation, in persons of a certain character of constitution. In hysteria, the globus, the tendency to cry or laugh, the disturbed breathing, the variously deranged state of the respiratory acts, all denote affection of most, if not all, the nerves coming from these segments. In chorea the frequent movements of the face and eyes, the peculiar and very characteristic mode of protruding the tongue, the impaired power of articulation, are dependent on an altered state of that part in which the portio dura of the seventh pair, the third, fourth, and sixth, and the ninth nerves are implanted. In both diseases the principal central disturbance is in the mesocephale; and this may be caused either by the direct influence of the mind upon it, or by the propagation of a state of irritation to it from some part of the periphery. Chorea, even of the most violent and general kind, is very commonly produced by sudden fright; and it is well known how frequently mental anxiety or excitement developes the paroxysm of hysteria.

There is no part of the cerebro-spinal centre which appears to exercise such extensive sway over the movements and sensations of the body as this portion, *the mesocephale*, which may be regarded as the centre of emotional actions. Its influence extends upwards to the cerebral convolutions—backwards to the cerebellum—downwards to all the nerves of sensation and motion. Through its connection with the posterior horns of the spinal grey matter, it can excite the sensitive as well as the motor nerves of the trunk. Hence it is not to be wondered at that a highly disturbed state of this centre is capable of deranging all the sensitive as well as motor phenomena of the body and even the intellect. Hence we may explain the extraordinary movements in hydrophobia and general chorea, in both of which diseases this part of the nervous centre is doubtless affected. It has often been remarked how much more powerful are the voluntary actions when prompted by some strong emotion, than when excited only by an effort of the will. Rage, or despair, is able to magnify the power of the muscles to an incalculable degree. This may be due to the increased stimulus derived from the influence of the centre of emotion being conjoined with that of the centre of volition.

The intimate connection of the olivary columns with the grey matter of the cord, and through that with all the roots of the spinal nerves, illustrates the power of emotional changes upon the organic processes. How often does the state of the feelings influence the quantity and quality of the secretions, no doubt through the power of the nerves over the capillary circulation! Blushing is produced through an affection of the mind, acting primarily on the centre of emotion, and through it on the nerves, which are distributed to the capillary vessels of the skin of the face.

The sexual passion must be ranked among the mental emotions. Like them, it may be excited and ministered to by a certain line of thought, or by particular physical states of the sexual organs. It seems, therefore, more correct to refer this emotion to the common centre of all, than to a special organ—according to Gall's theory; and it may be remarked, that great developement of this part of the brain is just as likely to produce great width of cranium in the occipital region as a large cerebellum.

Of the functions of the cerebellum.—All anatomists are agreed in admitting, in the whole vertebrate series, (the amphioxus, perhaps, excepted,*) the existence of a portion of the encephalon which is analogous to the cerebellum. This extensive existence of such an organ indicates its great physiological importance, as a special element of the encephalon. The cerebellum exhibits much difference both as regards size and complexity of structure in the different classes; and although, upon the whole, it increases in its developement in the same ratio as the hemispheric lobes, it exhibits no constant relation of size to those parts.

The large size and complicated structure of this organ in the higher vertebrate animals, and its distinctness from the cerebrum,—for its commissural connection with that segment of the encephalon is not extensive,—have excited the interest and curiosity of speculative physiologists; and, accordingly, we find no part respecting which a greater variety of hypotheses have been suggested, most of them being entirely devoid of foundation. The experiments of Flourens have, however, thrown more light on this subject than any previous observations; and his hypothesis appears nearer the truth than any which has been proposed.

The facility with which the cerebellum may be removed or injured, especially in birds, without involving the other segments of the brain, renders it a much more favourable object for direct experiment than them. A skilful operator may remove the greater part or the whole of the cerebellum without inflicting any injury on the hemispheres or other parts.

Flourens removed the cerebellum from pigeons by successive slices. During the removal of the superficial layers there appeared only a slight feebleness and want of harmony in the movements, without any expression of pain. On reaching the middle layers an almost universal agitation was manifested, without any sign of convulsion: the animal performed rapid and ill-regulated movements; it could hear and

* The observations of Quatrefages render it doubtful that even the amphioxus can be regarded as forming an exception. Ann. des Sc. Nat., 1846.

see. After the removal of the deepest layers, the animal lost completely the power of standing, walking, leaping, or flying. The power had been injured by the previous mutilations, but now it was completely gone. When placed upon his back, he was unable to rise. He did not, however, remain quiet and motionless, as pigeons deprived of the cerebral hemispheres do; but evinced an incessant restlessness, and an inability to accomplish any regular or definite movement. He could see the instrument raised to threaten him with a blow, and would make a thousand contortions to avoid it, but did not escape. Volition and sensation remained; the power of executing movements remained; but that of coordinating those movements into regular and combined actions was lost.

Animals deprived of the cerebellum are in a condition very similar to that of a drunken man, so far as relates to their power of locomotion. They are unable to produce that combination of action in different sets of muscles which is necessary to enable them to assume or maintain any attitudes. They cannot stand still for a moment; and, in attempting to walk, their gait is unsteady, they totter from side to side, and their progress is interrupted by frequent falls. The fruitless attempts which they make to stand or walk are sufficient proof that a certain degree of intelligence remains, and that voluntary power continues to be enjoyed.

Rolando had, previously to Flourens, observed effects of a similar nature consequent upon mutilation of the cerebellum. In none of his experiments was sensibility affected. The animal could see, but was unable to execute any of the movements necessary for locomotion.

Flourens' experiments have been confirmed by those of Hertwig in every particular, and they have been lately repeated with similar results by Budge and by Longet. The removal of part of the cerebellum appears capable of producing the same vertiginous affection which has been already noticed in the case of deep injuries to the mesocephale. After the well-known experiments of Magendie, of dividing either crus cerebelli, the animal was seen to roll over on its long axis towards the side on which the injury was inflicted.

The effects of injuries to the cerebellum, according to the reports of the experimenters above referred to, contrast in a very striking manner with those of the much more severe operation of removing the cerebral hemispheres. "Take two pigeons," says M. Longet; "from one remove completely the cerebral lobes, and from the other only half the cerebellum; the next day, the first will be firm upon his feet, the second will exhibit the unsteady and uncertain gait of drunkenness."

Experiment, then, appears strikingly to favour the conclusion which Flourens has drawn, namely, that the cerebellum possesses the power of coordinating the voluntary movements which originate in other parts of the cerebro-spinal centre, whether these movements have reference to locomotion or to other objects.

That this power is mental, *i. e.* dependent on a mental operation for its excitation and exercise, is rendered probable from the experience of our own sensations, and from the fact that the perfection of it requires practice. The voluntary movements of a new-born infant, although perfectly controllable by the will, are far from being coordinate: they are, on the contrary, remarkable for their vagueness and want of definition. Yet all the parts of the cerebro-spinal centre are well developed, except the cerebellum and the convolutions of the cerebrum. Now, the power of coordination improves earlier and more rapidly than the intellectual faculties; and we find, in accordance with Flourens' theory, that the cerebellum reaches its perfect developement of form and structure at a much earlier period than the hemispheres of the cerebrum.

It may be stated as favourable to this view of the mental nature of the power by which voluntary movements are coordinated, that, in the first moments of life, provision is made for the perfect performance of all those acts which are of the physical kind. Thus, respiration and deglutition are as perfect in the new-born infant as in the full-grown man; and the excitability of the nervous centres to physical impressions is much greater at the early age, partly perhaps in consequence of the little interference which is received at that period from the will.

That the cerebellum is an organ favourably disposed for regulating and coordinating all the voluntary movements of the frame is very apparent from anatomical facts. No other part of the encephalon has such extensive connections with the cerebro-spinal axis. It is connected slightly indeed with the hemispheres of the brain, by the processus cerebelli ad testes, but most extensively with the mesocephale, the medulla oblongata, and the spinal cord. Now it is not unworthy of notice that its connection with the brain proper is more immediately with that part, which may be regarded as the centre of sensation; namely, with the optic thalami. This connection of the cerebellum with the centre of sensation may probably have for its object to bring the muscular sense to bear upon the coordination of movements, in which the individual experience of every one shows that that sense must materially assist.

The cerebellum is brought into union with each segment of the great nervous centre upon which all the movements and sensations of the body depend; through the restiform bodies it is connected with the medulla oblongata and the spinal cord; by the fibres of the pons with the mesocephale, and thus with the anterior pyramids and corpora striata; and through the processus e cerebello ad testes with the optic thalami. What can be the object of these extensive connections? It would be difficult to conceive any function for which so elaborate a provision would be more necessary, than that of regulating and coordinating the infinitely complex movements which the muscular system is capable of effecting; more especially when it seems highly probable that the antero-lateral columns of the cord, and the anterior pyramids and olivary columns supply all the anatomical conditions necessary for the developement of acts of sensation and volition.

It thus appears that Flourens' views respecting the office of the cerebellum derive considerable support both from experiment and from anatomy. When we come to collect the evidence on this subject which has been furnished by the effects of disease, we obtain very little information of a satisfactory kind. A superficial lesion of either cerebellar hemisphere or of the median lobe does not cause paralysis, but may produce delirium or convulsions, as a superficial lesion of either cerebral hemisphere may; but a deep-seated lesion of the cerebellum involving the central white substance which is continued from the crus cerebelli causes hemiplegia on the opposite side. This similarity between the effects of cerebellar and of cerebral disease is a remarkable and highly interesting fact, but one which considerably increases the difficulty of obtaining from pathological phenomena any contribution to the solution of physiological questions. It may be explained thus:—the transverse fibres of the pons passing through the mesocephale would propagate to this segment the morbid influence of any deep-seated lesion of the cerebellum, and thus affect the adjacent pyramid, which again would affect the opposite half of the body just as if the morbid influence originated in the cerebral hemisphere. It is, then, this secondary affection of either pyramidal body which obscures the proper signs referable to cerebellar lesion.

A few cases, however, have been put on record, in which a tottering gait, like that of a drunken man, and a defective power of coordination existed in connection with a diseased state of cerebellum. A striking instance of this occurred under my own observation: a young surgeon, who had recently received an appointment in the medical service of the army, was in attendance in the military hospitals at Chatham, preparatory to his nomination to a regiment. It was observed that as he walked he staggered to so great a degree that he was suspected of drinking to excess, and was put under arrest on this account. It was soon, however, found that he was suffering under symptoms of diseased brain, and he was sent up to town and placed under my care. I found that his principal symptom was extreme difficulty in the coordination of his movements, accompanied by a sense of giddiness in the head. He could neither stand nor walk, yet there was no distinct paralysis, for while he was in the recumbent posture he could move about his limbs freely. After a time he became amaurotic and comatose. The post-mortem examination revealed softening of the left crus cerebri and a patch of yellow softening on the corresponding restiform body: there was in addition a recent deposit of lymph at the base of the brain around the optic commissure.

I must now notice two other hypotheses as to the office of the cerebellum; the first is that of Foville; the second that of Gall. Foville supposed that the cerebellum is the centre of sensation, "the focus of sensibility." The objections which appear fatal to this hypothesis are derived from anatomy and from pathological observation. The cerebellum wants that general connection with *sentient nerves,* (direct as well as indirect,) which might be expected if it performed the office in question. Not one of the nerves of pure sense has any connection with it. Moreover the diseased states of cerebellum do not give rise to any privation of sensibility such as might be expected where the centre of sensation was the part involved.

The most celebrated view of the office of the cerebellum is that put forward by the distinguished Gall. He supposed that the instinct of propagation has its seat in this organ, and therefore referred to it as the source of all sexual and generative impulses.

Gall's view rests on two assumptions; first, that the instinct of generation or of reproduction is "the most indispensable and most powerful of all the instincts;" and, secondly, that great width of the occipital region of the skull and thickness of the back of the neck indicate great developement of the cerebellum.

It is by reason of the assumed transcendant importance of the generative instinct that so large a portion of the encephalic mass (an eighth or ninth part of the whole) has been assigned by Gall to exercise an exclusive influence over it.

This first position taken by Gall seems to me untenable. Can we separate the sexual instinct from the emotions, from those especially which are clearly instinctive in their nature? I apprehend not. The same part of the brain would probably exercise its influence upon all the emotional actions. But even if the sexual instinct were separable from the other instincts, it seems very questionable whether it is of that paramount importance as to need a separate organ of great magnitude, of complex structure, and of extensive connections with the rest of the cerebro-spinal centre. If we compare it with the instinct of self-preservation, as manifested in providing either for the wants of the body or for defence against assault, it certainly cannot be admitted to have a superior influence to this the most pressing of all. Yet, even to this instinct, a separate seat has not been assigned in the brain.*

The second position which Gall assumes,

* This argument was used, nearly *totidem verbis,* in Mr. Bowman's and my Physiology in discussing this subject. It and other objections to Gall's doctrine, which we made, have been criticised by Mr. Noble, of Manchester, a most zealous phrenologist, who, like many of that school, is impatient of the slowness of belief of those who do not completely embrace the opinions which he advocates. Mr. Noble seems to think that the existence of a surmise of Spurzheim's, of a single recorded observation of Dr. A. Combe, which led him to *suggest* that a certain large convolution, seen by him in the brain of a lady who had great *fear of death,* who evinced "perpetual anxiety about her own *death,*" should be assigned as the seat of a faculty to be called "*love of life,*" and some observations of Dr. Vimont, which Mr. Noble does not value so much as the *single* observation

and which is certainly necessary to the validity of some of the premises upon which his doctrine rests, is, I think, likewise open to strong objection. I cannot understand that great width of the occipital region and thickness of the back of the neck should necessarily indicate a great developement of the cerebellum. I do not mean to assert that a large cerebellum would not give rise to a large occipital region, but I do assert that great developement of the mesocephale may give rise to the very same external indications. This latter segment of the encephalon is of considerable size, and, as I have shown in a former part of this article, of complex anatomical structure, and contains all the elements of a distinct centre, while it possesses extensive connections with the cerebral hemispheres, the cerebellum, and the medulla oblongata. The largest portion of it, however, is independent of the cerebellum, and it is this portion which contains the greatest abundance of vesicular matter, and which has most distinctly the characters of a separate centre of nervous influence. Now the position of the mesochephale, in front of and between the hemispheres of the cerebellum, is such that a great developement of it would push the hemispheres to each side, and thus, notwithstanding a small size of the hemispheres themselves, the occipital region would become expanded.

The great and pre-eminent size of the cerebellum in the human subject would warrant the belief that the sexual instinct in man far exceeded that of other animals, if Gall's doctrine were correct. Yet this seems by no means to be the case; for, although in man this instinct is more frequently in operation, it cannot be said to influence the whole system to the same extent as in many of the inferior animals. Surely this instinct is not more powerful in man than in the feline class, both male and female;—the common cat, for instance, in which the lateral lobes of the cerebellum are very imperfectly developed! There are other animals, likewise, peculiarly distinguished by the strength of this instinct and the remarkable extent to which it influences their entire functions. I have already referred to the extraordinary state of polar tension to which the spinal cord of the male frog, or a portion of it, is liable during the state of sexual excitement. Yet in this animal the cerebellum is very small; nor does it at this period acquire any increase of size; and, moreover, there is no appreciable difference between the cerebellum of the male frog and that of the female, which exhibits no indication of increased excitement at this period. In fishes the instinct is in all probability strong; and the generative impulse, unaided as it is by sexual commerce, would seem to be dependent, more than in cases where copulation occurs, on the change which may take place in the nervous centre in accordance with the manifestation of that instinct; yet the cerebellum is by no means large in these animals. Dr. Carpenter refers to the kangaroo as affording a good instance of disproportionate developement of the cerebellum to the generative instinct. He says, " a friend who kept some kangaroos in his garden, informed the author that they were the most salacious animals he ever saw, yet their cerebellum is one of the smallest to be found in the class (Mammalia). Every one knows, again, the salacity of monkeys; there are many which are excited to violent demonstrations, by the sight even of a human female; and there are few which do not practise masturbation when kept in solitary confinement; yet in them the cerebellum is much smaller than in man, in whom the sexual impulse is much less violent."

According to Gall and most of his followers mutilation of the genital organs or their decay in the advance of age is attended by marked effects on the cerebellum. If one testicle be destroyed, a distinct diminution, according to Gall, takes place subsequently in the cerebellar hemisphere of the opposite side. The kind of evidence upon which phrenologists rest their views of this matter will appear from the following specimens: 1. Dr. Gall relates that at Vienna he was consulted by two officers who had become impotent in consequence of blows from fire-arms, which had grazed the napes of their necks. 2. " Baron Larrey," says Gall, "sent to me a soldier who, in undergoing an operation for hernia, had lost the right testicle. Several years afterwards his right eye became weak. He began to squint with the diseased eye, and could scarcely any longer distinguish objects with this eye. I examined the nape of his neck, in presence of the two physicians who had brought him, and I found *the occipital swelling of the left side much less prominent* than that of the right side. The difference was so perceptible that the two physicians were struck with it at first sight." 3. Baron Larrey's cases:—*a.* An artilleryman received a wound from a musket-ball, which traversed from side to side the insertions of the extensor muscles of the head, grazing and dividing the two inferior occipital swellings which correspond to the hemispheres of the cerebellum. This individual experienced *a diminution in the size of his testicles, which fell into a state of atrophy.* *b.* A light horseman, of very amorous disposition, received a sword-cut, which divided the skin and all the convex portion of the occipital bone through to the dura mater. The right lobe of the cerebellum was seen through the opening of the dura mater, and the slightest pressure upon this organ

of Dr. Combe, justify him in charging us with ignorance in making this assertion. Mr. Noble likewise dignifies our argument with the title of " nonsense." I am content to repeat the argument and to leave it to persons of calmer judgment to decide whether it is of sufficient weight. Mr. Noble has been so courteous and so complimentary in his remarks generally, that I cannot allow myself to believe that he *intended* offence by the use of this term. I hope, however, that he will excuse me for observing that it is much to be regretted that the advocates of particular views should allow their zeal so far to outrun their judgment as to lead them, in the sober seriousness of print, to make use of terms which they would hardly venture upon in the less premeditated colloquial argument.—See Noble on the Brain, p. 142.

caused giddiness, fainting, and convulsive movements. The patient loses sight and hearing of the right side, experiences acute pain in the course of the dorsal spine, and *tingling in the testes, which in fifteen days were reduced to the size of a bean.* The patient dies of tetanus, with loss of the functions of sight, hearing, and generation.* On dissection there was great loss of substance at the occiput, *the medulla oblongata and upper part of the spinal cord were of dull white, of firmer consistence, and reduced in size one-fourth.* The nerves arising from these parts were likewise wasted. *c.* A chasseur received a sabre cut, which divided the skin and *external protuberance of the occipital bone*, and the extensor muscles of the head *as low down as the sixth vertebra.* This man gets well, but Larrey states that he declares "that he has been deprived of his generative powers ever since that wound." 4. Gall caused rabbits to be castrated, some on the right side and others on the left. Having had them killed six or eight months afterwards, he finds diminution of the cerebellar lobe opposite the removed testicle, and flattening of the corresponding occipital swelling. Vimont, however, found no diminution of the opposite lobe of the cerebellum in four rabbits on which castration had been effected on one side, and which had been kept *eight* months; but in four other rabbits, similarly treated, but kept *eighteen* months, a very perceptible diminution in the opposite lobe of the cerebellum was found.†

The results of mutilation of the generative organs, as obtained by the researches of M. Leuret, are far from being favourable to Gall's theory. M. Leuret took the weight of the cerebellum both absolutely, and, as compared with that of the cerebrum, in ten stallions, twelve mares, and twenty-one geldings. The following table shows the results of the absolute weights.

	Average.		Highest.		Lowest.
Stallions..	61	..	65	..	56
Mares....	61	..	66	..	58
Geldings..	70	..	76	..	64

Thus the remarkable result is obtained, that castration tends to augment the weight of the cerebellum, and not to reduce it, as Gall and his followers affirm.

What is further very remarkable in these researches is that the *cerebrum* in geldings is on the average less in weight than that in stallions; and the fact gives great confirmation to the results of weighing the cerebella, rendering it in the highest degree improbable that the excess of weight in the cerebellum was accidental.

The general expression of the facts obtained by Leuret is this, that in horses, mutilated as regards the principal generative organs, the cerebellum is heavier than in horses and mares not mutilated in the generative organ; and he compared twenty-one of the former with twenty-two of the latter.

* I apprehend the loss of the generative function is not uncommon in tetanus!

† Quoted from Mr. Noble on the brain.

Compare these observations with those above quoted from Gall by Mr. Noble, a most ardent phrenologist, and I think most unprejudiced persons will admit that in the number of observations, in the exactness with which those observations were conducted, and in their freedom from sources of fallacy, the researches of M. Leuret have greatly the advantage over those upon which Gall rests his conclusion.

Yet Mr. Noble, while he unhesitatingly accepts the few and very feeble instances quoted and adopted by Gall, is at great pains to depreciate these observations of Leuret; first, because they are not sufficiently numerous; secondly, because Mr. Parchappe found that, in comparing the cerebra and cerebella of a certain number of mad men and women with those of sane men and women, a very slight advantage existed in favour of the former; and, thirdly, because the author of the observations is an opponent of phrenology.

I must say, however, upon this point, that, while I do not reckon myself among the opponents to phrenology, but rather among those who are anxiously looking for and desirous of promoting a truly scientific phrenology,* I cannot but regard the facts brought forward by M. Leuret as of the greatest interest and importance, and not to be affected by any such arguments as those of Mr. Noble; nor are they to be met at all, save by similar weighings, in the same, or still better, in double the number of animals.

The last point to be noticed with regard to Gall's theory of the office of the cerebellum is that it certainly derives no support from pathological observations. The few cases quoted by Gall, in which the injury in the neighbourhood of the cerebellum seemed to affect sexual instinct are far from being conclusive, for they might apply equally, if it were assumed that the seat of the instinct were in the posterior lobes of the cerebrum, in the medulla oblongata, or in the spinal cord. Indeed Baron Larrey's second case is much more favourable to the localization of the generative impulse in the centre of emotions, than in the cerebellum. For the latter organ was free from disease, whilst the medulla oblongata was indurated. And, further, the assumed connection between

* The following passage from Dr. Holland's valuable "Medical Notes and Reflections" expresses so well the true position of phrenology, that I am glad to quote it as an excellent expression of my own creed relative to this point. "In the present state of our knowledge of the brain," says Dr. Holland, "and of its relation to the mental functions, an impartial view of phrenology requires, not that the doctrine should be put aside altogether, but that great abatement should be made of its pretensions as a system. To say the least, it is chargeable with what Lord Bacon has called 'an over-early and peremptory reduction into acts and methods,' and with the adoption of various conclusions not warranted by any sufficient evidence. But on a subject thus obscure in all its parts, and where our actual knowledge is still limited to detached facts or presumptions, there is enough to justify the opinion being kept before us, as one of the outlines to which future observations may apply; not fettered, as they now are, by the trammels of a premature arrangement." P. 517.

the generative instinct and the cerebellum, from the occasional existence of an abnormal erection of the penis, is not justified by the facts. This symptom is far from being constant in cerebellar disease—indeed it occurs in but a very small number of cases—and, as a symptom pointing to lesion of a particular portion of the cerebro-spinal axis, it is much more indicative of disease of the medulla oblongata or of the cervical portion of the spinal cord.

Office of the cerebral convolutions.—The great sheet of vesicular matter which forms the cortex of the human brain, is of such vast extent that it is forced to assume the convoluted form in order to its being packed within the ordinary compass of the cranium. A little consideration will shew that the *convoluted form* can be regarded no otherwise than as a convenient mode of packing, and that the *number* and *depth* of the convolutions are the best indications of the superficial extent of this expanse of vesicular matter. In certain cases a slow and gradual accumulation of water within the ventricles of the brain, causing a corresponding enlargement of the cranium, expands the matter of the cerebral hemispheres, by which the ventricles are enclosed, and the convolutions become unfolded. We thus obtain a distinct demonstration of the true arrangement of this part of the hemisphere, which must be regarded as a nervous centre, consisting of a vast mass of the potential vesicular matter freely supplied with bloodvessels from a vascular surface on its exterior (the pia mater), and giving rise to an infinite multitude of nerve-fibres, which pass from its internal surface to the corpora striata and optic thalami, the centres of volition and sensation. The name which Mr. Solly has given to this expanse of nervous matter, *hemispherical ganglion*, is very expressive, not only of its true character as a centre of nervous power, but likewise of the *unity* of the organ on each side, consisting as it does of an uninterrupted layer of vesicular matter with its emerging or immerging fibres, and not of a great number of different organs, as the term convolutions would imply.

This vesicular surface with the fibrous matter which connects it with the optic thalami and corpora striata forms by far the largest portion of the encephalon in the higher classes of animals. This fact alone ought to stamp it with great physiological importance. But, further, it is a well-proved fact, that *the complexity of the convolutions in the animal scale is in the direct ratio with the advance of intelligence*. At the same time it must be remembered that the complexity of the convolutions is in part determined by the size of the head and the capacity of the cranium. If, for example, the habits and mode of life of the animal require a small head and at the same time a certain degree of intelligence, the brain would exhibit a greater number and complication of convolutions than would be found in an animal of corresponding intelligence, but which required and possessed a larger head. Hence neither the *size* nor the *weight* of the brain, whether absolute or in relation to the body, affords any certain criterion of the extent of the convoluted surface. Highly complicated convolutions may exist along with a brain both absolutely and relatively small. Thus, the ferret, as shown by Leuret, whose habits require a small head, has several well-marked convolutions on each hemisphere, and a brain no larger than that of the squirrel, which has no convolutions at all, and which wants even the few fissures which mark their first developement in the rabbit, the beaver, the agouti, &c. And the last-named animals have the brain both absolutely and relatively larger than that of the cat, the pole-cat, the roussette, the unau, the sloth, and the pangolin, all of which possess convolutions.

At the early periods of human life, in infancy and childhood, the convolutions of the brain are very imperfectly developed, but their increase of size goes on simultaneously with the advance of mental power. If the former be arrested, or if some congenital fault prevent the further growth of the convolutions, the mental powers are of the lowest and feeblest kind, but little or not at all above those of the brute with imperfect convolutions. In all idiots the brain is not only small, but its convoluted surface is extremely limited.

Anatomy points to the conclusion that the office of the convolutions is connected with the functions of the mind. Perception, memory, the power of abstraction, judgment, imagination, all possess, as instruments of corporeal action, these folds of vesicular matter. And it seems not improbable that the phrenological view which assigns to certain convolutions a special office connected with some particular faculty or faculties is true. This is strongly supported by the fact of a regular disposition of certain primary convolutions in the various classes of animals, so that each form of brain has its proper convolutions, and that in tracing the convolutions from the most simple to the most complex, indications are found of the persistence of the primary and fundamental convolutions in the midst of many secondary and superadded ones.

It may be here mentioned that Gall was by no means the first to assign this function to the convolutions. Our countryman, Willis, in the seventeenth century, distinctly advanced this opinion, and conjectured that the various gyrations were intended for retaining the animal spirits "for the various acts of imagination and memory" within certain limits.

It is important to ascertain the endowments of the fibres which connect the vesicular surface of the convolutions to the corpora striata and optic thalami. They might be supposed to possess similar endowments to those of sensitive and motor nerves, if we adopted the views of those who hold that all the nerves are continued up into the brain. This point, however, has been settled in the most decisive manner by experiments, dating as far back as the time of Lorry.* Mechanical injury to them excites

* Mém. de l'Acad. des Sciences, 1760.

neither pain nor disturbance of motion. Even the electric current passed through them produces no sensible effect (Matteucci). We are led, therefore, to the conclusion that these fibres have endowments quite distinct from those of sensitive and motor nerves, (a fact, by the way, quite irreconcileable with the doctrine which makes the brain the concourse of these fibres,) and that they are internuncial between parts which are beyond the *immediate* influence of the ordinary physical agents, and which have no direct connection with muscular organs. The proper stimulant of these fibres is the mind on the one hand, or the nutrient changes in the brain on the other. But, under the influence of a continued morbid irritation, they may excite either pain or convulsion, or both, as is frequently the case in disease of the cerebral meninges; this, however, is effected through a change produced in the corpora striata and optic thalami, and propagated thence to the origins of motor and sensitive nerves, or through irritation of the nerves of the meninges, which affect the centres of motion and sensation, just as the nerves of other parts do.

The experiments of Flourens and of Hertwig show that removal of the cerebral hemispheres produces a state of stupor, and, to use Flourens' expression, as it were condemns the animal to perpetual sleep, but deprives it even of the faculty of dreaming. There is, however, no paralytic state produced by these mutilations. It is evident, then, that the effect of these experiments is *psychical*, and it may be adduced as confirmatory of the view which associates the functions of the cerebral convolutions with the operations of the mind.

Pathological anatomy affords interesting confirmation to this view. Inflammation of the membranes of the brain, more especially of the pia mater, is invariably attended by disturbance of the mental faculties, as manifested by more or less delirium. It appears that any material alteration of the circulation in the grey matter of the convolutions is capable of giving rise to delirium; in the instance above quoted, the circulation in this part is affected in consequence of the inflammation of the pia mater, the bloodvessels of the one being distinctly continuous with those of the other; but in other instances of violent delirium, such, for example, as delirium tremens, the vesicular matter of the convolutions is found after death to be bloodless, as if its wonted supply of blood had been cut off or abstracted from it. We find this state in the delirium after great operations, after puerperal floodings, in the delirium of rheumatic fever, and in that of gout, and likewise in that which occurs in the more advanced stages of fever.

We learn from the most trustworthy reports of the dissections of the brains of lunatics that there is invariably found more or less disease of the vesicular surface and of the pia mater and arachnoid in connection with it, denoted by opacity and thickening of the latter with altered colour or consistence of the former.

From these premises it may be laid down as a just conclusion that the convolutions of the brain, in other words, that vast sheet of vesicular matter which crowns the convoluted surface of the hemispheres, constitute the *centre of intellectual action*, as distinguished from the *centre of volition* and the *centre of sensation* (corpora striata and optic thalami). It is essential to the perfection of cerebral action that these centres should be connected, and that the *centre of intellectual action* should be capable of exciting or of being excited by the centres of volition and sensation. This connection and mutual influence is effected through the innumerable fibres which pass from the one to the other.

To determine the precise connection which exists between the mind and the brain is beyond the reach of our means of observation and experiment. All we are justified in affirming is that the mental acts are associated with this portion of the brain, which I would call *the centre of intellectual actions;* and that the integrity of this part is necessary to the perfect exercise of the mind; that, in the language of Cuvier, this centre is the sole receptacle in which the various sensations may be as it were consummated, and where all sensations take a distinct form and leave lasting traces of their impression, serving as a seat to memory, a property by means of which the animal is furnished with materials for his judgment.

The actions of the convoluted surface of the brain, and of the fibres connected with it, belong altogether to the class of *mental* nervous actions; that is, they either excite or are excited by mental change. The physical changes in these parts give rise to a corresponding manifestation of ideas, and every thought is accompanied by a change in this centre. Modifications in its nutrition, or interruptions to it, produce corresponding effects on the mind. An increased activity of nutrient change causes a rapid developement of ideas, which, being generally uncontrollable by the will, and therefore undirected, assumes the form of raving or delirium. The shock of concussion so far checks the organic changes of the vesicular surface, and perhaps also of the fibrous matter, as to interrupt for a time those conjoint actions of the mind and the brain which are necessary for perfect consciousness. The condensation of the substance of the hemispheres, which is produced by an apoplectic clot, or by the effusion of some other foreign matter, prevents a similar consent of action, and thus gives rise to the phenomena of *coma*, a state in which all mental nervous actions are destroyed or suspended, and which, if continued long enough, will annihilate the physical nervous actions likewise.

It will be observed that, in this description, the workings of the mind are not viewed as mere functions of the brain. The term Mind expresses the mode of action of the Soul, an entity which both reason and revelation assure us is essentially different from the Body,* being incorruptible and indestructible, in the sense in which we suppose that both corruption and destruction may affect material things. To

* *Ens incorporeæ prosapiæ,* Prochaska.

will, to feel, to perceive, to think, are so many states of Soul or acts of Mind.

Mind is, then, the mode of action of the Soul, as Life is the mode of action of the Body. The latter we distinguish as *material*, and the phenomena of life as specially belonging to organized matter; the former we denominate *immaterial*, to mark its essential difference from the body, admitting, however, that it exists in a mysterious union with the nervous system of the body in a manner so intimate that in a state of health the smallest change in either readily affects the other.

Such is the doctrine which seems most consonant with reason and experience, and, above all, with revelation. But there are those who maintain that not only are certain states of mind preceded by certain states of body, but that all our ideas, our sensations, our volitions, are the result of, and as it were generated by, certain organic changes.

This view, which is that of materialism, while it necessarily tends to destroy our hopes of a future life, by denying even the very existence of a Soul, and not its immortality only, is opposed by the consciousness which we possess of a power inherent in the mind to direct and control the actions of the brain, and by the knowledge that the mind will rise superior to the fatigue and exhaustion of the body, and will survive, unimpaired, even its wreck.

There are, moreover, some excellent persons, who, while they admit the existence of an immortal soul distinct from the mind, nevertheless regard the phenomena of the mind as functions of the brain, resulting from the changes which are continually taking place in that organ. The mind, they say, is "the aggregate of the functions of the brain," and is entirely dependent on its integrity. But the adoption of these views involves the advocate of them in as great a difficulty as that from which he flatters himself he has escaped. If there be a soul, what is its relation to the mind? What is its office? Is it simply associated with the body without being affected by it or affecting it in turn? Surely it must have some office, and if it be admitted to be capable of exercising any influence, either on the mind or on the body, then the whole matter in dispute vanishes. If the soul can affect the mind, it must do so according to these views through the body; and, if this be admitted, why make a difficulty about admitting that the will, as a faculty of the soul, can influence some portion of the brain?

On the other hand, if it be denied that the soul can affect either mind or body, then must we come to the conclusion that the soul is inert, or else an entity totally distinct from the body, a looker-on as it were, which watches the corporeal functions and the mental phenomena, but takes no part in them, and has no true sympathy with them.*

An acute and ingenious writer, Dr. Wigan, who has advocated with great zeal and ability the docrine of the duality of the mind, seems to think that the progress of mental philosophy and of cerebral physiology is much hindered by the views of those who advocate the spiritual

* I beg the reader to peruse with attention the following passage from Bishop Butler:—"Human creatures," says this profound thinker, "exist at present in two states of life and perception, greatly different from each other; each of which has its own peculiar laws, and its own peculiar enjoyments and sufferings. When any of our senses are affected or appetites gratified with the objects of them, we may be said to exist or live in a state of sensation. When none of our senses are affected or appetites gratified, and yet we perceive and reason and act, we may be said to exist or live in a state of reflexion. Now, it is by no means certain that any thing which is dissolved by death is any way necessary to the living being in this its state of reflection, after ideas are gained. For though, from our present constitution and condition of being, our external organs of sense are necessary for conveying in ideas to our reflecting powers, as carriages, and levers, and scaffolds are in architecture, yet when these ideas are brought in, we are capable of reflecting in the most intense degree, and of enjoying the greatest pleasure and feeling the greatest pain by means of that reflection without any assistance from our senses; and without any at all, which we know of, from that body which shall be dissolved by death. It does not appear then, that the relation of this gross body to the reflecting being is, in any degree, necessary to thinking—to our intellectual enjoyments or sufferings; nor, consequently, that the dissolution or alienation of the former by death will be the destruction of those present powers which render us capable of this state of reflection. Further, there are instances of mortal diseases which do not at all affect our present intellectual powers; and this affords a presumption that those diseases will not destroy these present powers. Indeed, from the observations made above, it appears that there is no presumption that the dissolution of the body is the destruction of the living agent from their mutually affecting each other. And, by the same reasoning, it must appear too that there is no presumption that the dissolution of the body is the destruction of our present reflecting powers from their mutually affecting each other; but instances of their not affecting each other afford a presumption of the contrary. Instances of mortal diseases not impairing our present reflecting powers evidently turn our thoughts even from imagining such diseases to be the destruction of them. Several things, indeed, greatly affect all our living powers, and at length suspend the exercise of them; as for instance drowsiness increasing till it ends in sound sleep; and from hence we might have imagined it would destroy them, till we found by experience the weakness of this way of judging. But, in the diseases now mentioned, there is not so much as this shadow of probability to lead us to any such conclusion as to the reflecting powers which we have at present. For, in those diseases, persons, the moment before death, appear to be in the highest vigour of life. They discover apprehension, memory, reason, all entire; with the utmost force of affection; sense of character, of shame and honour; and the highest mental enjoyments and sufferings, even to the last gasp; and these surely prove even greater vigour of life than bodily strength does. Now what pretence is there for thinking that a progressive disease when arrived to such a degree, I mean that degree which is mortal, will destroy those powers which were not impaired, which were not affected by it during its whole progress quite up to that degree? And if death by diseases of this kind is not the destruction of our present reflecting powers, 't will scarce be thought that death by any other means is." See the admirable chapter, "*Of a future Life*," in Butler's Analogy of Religion, natural and revealed.

nature of the mind.* But no doubt his fears are unfounded; for if we hold that a connection subsists between soul and brain so intimate that every change in either affects the other more or less, surely the strongest inducement is held out for the minutest investigation of the organ which can exercise so wonderful an influence on the immortal part of our nature.

I would, then, lay it down that the proper function of the brain is to generate the nervous force, and that that force affects the soul and excites its action for the developement of mental phenomena. On the other hand, the action of the soul affects the brain, exciting it to the developement of nervous force, and directing that force for the production or regulation of other corporeal phenomena.

Taking this view of the nature of the mind, and of the relation of mind and body, we may, with advantage, arrange the principal mental states into two classes, according as they are preceded by certain states of body, or as they precede and are capable of exciting certain states of body.

In the first class I would place *sensation*, and such mental states as are immediately associated with or produced by sensation, as the emotions and the passions. To this class I would likewise refer that peculiar power which is, with the highest probability, exercised by the cerebellum, and to which we must give the name of balancing or coordinating power. It is a power which, like the emotions and passions, is exercised without any previous train of thought or intellectual process, and seems simply to be evolved as an immediate consequence of certain sensations, which are developed under the influence of impressions made upon the organs which are to be submitted to its regulation. Thus, in locomotion, the exercise of the muscles produces the sensation upon which the evolution of this mental power depends, which reacts upon the same muscles with an intensity proportionate to the exciting impulse. In the exercise of this power there is much analogy with the ordinary reflex acts; but while the latter are purely physical in their nature, the former may be clearly shown to be mental. The proofs of this are derived, 1, from its being never accomplished without consciousness; 2, from its being always associated with volition; 3, from the curious differences in the mode of its exercise in different individuals, according to differences of mental and physical constitution, one man being expert and precise in all his movements, another awkward and clumsy; 4, from the marked improvement which may be effected in it by instruction and duly regulated practice.

In the second class I would place volition and attention. In these the mind has clearly the initiative, and is capable of inducing certain states of body, either to move certain organs (voluntary motion), or to concentrate one or more of the inlets of sensation upon some external objects (attention). The power of abstraction, imagination, and all purely intellectual processes, are obviously associated with these.

The symmetrical disposition of the parts of the encephalon on each side of the median plane has been recognised by all anatomists. This symmetry is so complete that we may, with perfect correctness, speak of two brains, a right and a left brain, which are united to each other by transverse commissures. The right brain corresponds exactly with the left, just as much as the right eye corresponds with the left. This doubleness of the brain, no doubt, accords curiously with the doubleness of all the organs of sense, and very probably is rendered necessary by the existence of the double set of inlets to sensation. It is remarkable, however, that a perfect symmetry of the convolutions is not found in the higher races of mankind, and in individuals of high intellectual powers; and that the greater the mental power, the less symmetrical are the convolutions. In the inferior races, on the other hand, as Tiedemann has well shown, the symmetry of the convolutions is exact.

Upon the proved existence of two brains, as thus explained, Dr. Wigan, adopting the materialist view of mental phenomena, rests the theory that the mind is dual; that we have two minds; that each brain performs its own mental functions, which are in perfect harmony, if the two brains harmonise in quality, structure, and action.

It cannot be doubted that two brains, thus symmetrical in structure, must have a tantamount symmetry of function, if I may be allowed the expression; and that, therefore, in order to insure harmony of action between them, and to prevent the actions of one from interfering with or neutralising those of the other, some such organic connection between them is necessary as that which exists between the two retinæ, and which converts the separate and in some degree dissimilar physical impressions made on each of them into one sensation.

And as any interference with the organic conditions necessary to secure single vision with two eyes produces double vision, so it is not unreasonable to expect that an analogous imperfection in the organic union between the two brains may occasion doubleness of mental impression and action. Such a conclusion, as Dr. Wigan has ingeniously suggested, gives the clue to the explanation of such phenomena as states of double consciousness, delusions, irregular volitions, and some forms of insanity; and, if fairly worked out by physiological psychologists, may solve other obscurities connected with the phenomena of the mind. While, therefore, I admit that great practical interest and value attach to Dr. Wigan's views respecting the action of two brains, I am not prepared to infer the existence of two minds from that of two brains; no more than I can assume a duality of our visual sense from the existence of two eyes. The two cases, indeed, are strictly analogous. The organic change in each retina developes a

* Wigan on the Duality of the Mind. Lond., 1844.

corresponding sensorial impression; and from the connections which subsist between the retinæ, and still more from that between the centres of sensation, these impressions become fused into one. In like manner the organic changes in the two brains developing nervous force in similar modes and proportions, each being capable of affecting the mind similarly, although perhaps not identically, are yet so united in their action that the double organic affection acts on the mind as one. But if, through default of the connecting media of the two brains, or through lesion of one, the organic changes in each do not harmonise with those in its fellow, then it is plain that two separate and distinct mental affections will result, and more or less of confusion must ensue. I can see no ground for inferring the existence of two minds from such a supposition. The confusion results from the want of simultaneous affection of the same mind by two distinct and separate brains. If, in vision, each centre of sensation affected only its own mind, or, in other words, developed only its own mental phenomena, as Dr. Wigan's theory would compel us to assume, then each mind would perceive a different perspective projection of the object presented to the eyes, and an elaborate and complex mental process would be required to combine the two sensorial impressions. How much simpler is the view of this process which assigns the combination of the double impression to a physical union in the brain of each physical change in the retina; so that, in truth, but one impression, different from each of its excitant ones, reaches the mind. So also, in the normal intellectual action, the organic changes of the two brains are united by the various transverse commissures, so that but one physical stimulus affects the mind and excites but one train of thought. Not so, however, when from any defect in the brains themselves, or in the commissures, the physical conditions necessary for the organic states of the two brains cannot be fulfilled.

Dr. Wigan's theory is inconsistent with the acknowledged fact of the existence of an imperfect symmetry of the convolutions in persons possessing the highest order of mind. If the two brains always act in harmony, there ought to be perfect symmetry. But if we admit that the mind may have the initiative, then it is easy to understand how one brain may be used more than another.

That a power exists of using one brain more than another, seems probable from the more frequent and more perfect use of one hand; and the existence of such a power implies also a capability of keeping one brain in suspense while the other is acting, under particular circumstances, just as we can suspend the use of one arm or one finger or one eye, although the exercise of its fellow prompts greatly to its simultaneous action.

Sleep is an affection of the centre of intellectual action, a condition rendered necessary by the incessant working of the mind. It is indicated by the cessation of all mental nervous actions. In deep sleep the body is given up to the physical nervous actions only, without which the functions of breathing, circulation, &c., could not be carried on. *Dreaming* occurs only in imperfect sleep,—often, if not always, just before waking,—and serves to show how the organic changes of the centre of intellectual action, when uncontrolled, may produce the most rapid trains of thought, recalling events or impressions that have passed away, and which we may have thought had been forgotten.

Coma is sleep of the profoundest kind, a paralysis, indeed, of the centre of intellectual action, as well as of sensation and volition. It occurs under states of disease, which induce *compression* of the brain, or under states of shock, which suspend or greatly diminish its natural changes, as in concussion. Or it may be induced by the influence of certain poisons of the sedative or narcotic kind, as opium and belladonna, which, if given in too large a dose, paralyse first the centres of mental nervous actions, and ultimately those of physical nervous actions.

Somnambulism must be regarded as a state of intense dreaming, in which the person is prompted to the performance of certain acts. Talking in one's sleep, the curious changes of position which are made under the influence of nightmare, and even the most complex actions, as walking, or taking things from one place to another, or holding a long conversation, are all induced by the same state, a morbid condition of the centre of intellectual action, generally produced by deranged assimilation or great previous disturbance of mind. The somnambulist, in short, is one who dreams and acts in his dream as if he were awake, and as if all the phenomena of which he takes cognizance were real.

Delirium is a condition very analogous to dreaming. The organic changes in the centre of intellectual action are too rapid to be controlled by the will, or the influence of the centre of volition is impaired. The ravings of a delirious patient generally take place unconsciously, as if the centre of sensation were impaired likewise. In most instances, however, the patient may be roused; a strong stimulus, as in addressing him with a loud voice, will affect his centre of sensation, and he either controls his thoughts for a brief space, and directs his attention to what is going on, or the effect of the stimulus is to direct his ravings into some new channel. The incoherent and unconnected manner in which thought follows thought in the delirious state is sufficient proof that the centre of intellectual action requires the controlling power of a will for perfect trains of thought, as much as any particular set of muscles requires the same influence for the accomplishment of definite action.

Delirium, indeed, may be viewed as a *subjective* phenomenon of the centre of intellectual action, just as *tinnitus aurium* or *ocular spectra* are subjective phenomena of the centre of sensation.

In analysing the fibres of the centrum ovale we find that a large number of them is commissural, but that the greates proportion of them serves to establish a communication between the centre of intellectual action, and the centres of volition and sensation. It is through this connection that the intellect and the will are capable of mutually affecting each other, the intellect prompting or exciting the will; and the will, on the other hand, controlling or applying the powers of the intellect. The faculty of attention, and, therefore, in a certain degree, that of memory, are dependent on the influence of the centre of volition upon the centre of intellectual action. Every one is sensible of a power which he possesses of fixing his attention on any given subject, as distinct as that by which he can contract any particular muscle. The association of the intellectual centre with that of sensation is necessary to ensure the full perception of sensitive impressions. The experience of each individual can supply him with numberless instances in which, while the mind was employed upon some other object of interest, an impression was made upon some one of the organs of sense, and indistinctly *felt*, but not fully perceived. When the mind has become disengaged, the fact that an impression had been made is recalled, without any ability to recollect its precise nature. And in many lunatics the centre of intellectual action is so impaired as to destroy or greatly reduce the power of perception, whilst there is abundant evidence to shew that the affections of the organs of sense make a sufficient impression on the centre of sensation, although in such cases this centre may likewise participate in the general hebetude.

Perfect power of speech, that is, of expressing our thoughts in suitable language, depends upon the due relation between the centre of volition and that of intellectual action. The latter centre may have full power to frame the thought; but, unless it can prompt the will to a certain mode of sustained action, the organs of speech cannot be brought into play. A loss of the power of speech is frequently a precursor of more extensive derangement of sensation and motion. In some cases the intellect seems clear, but the patient is utterly unable to express his thoughts; and in others there is more or less of mental confusion. The want of consent between the centre of intellectual action and of volition is equally apparent in cases of this description, from the inability of the patients to commit their thoughts to writing.

The hemispheres of the brain, as has been already stated, are insensible to pain from mechanical division or irritation; in wounds of the cranium in the human subject, pieces of the brain which had protruded have been removed without the knowledge of the patient. Nevertheless, pain is felt in certain lesions of the brain, even when seated in the substance of the hemispheres, or in the optic thalami or corpora striata. This results from the morbid irritation extending to other parts with which nerves are connected, as the medulla oblongata; or in which nerves are distributed, as the membranes. The nearer a cerebral lesion is to the membranes or to the medulla oblongata, the more likely is it to excite pain. Headaches, of whatever nature, must be referred to irritation, either at their centres or at their periphery, of those nerves which are developed in the dura mater or in the scalp. The branches of the fifth pair, of the occipital nerve, and the auricular branch of the cervical plexus, are those most frequently affected.

Certain sensations are referred to the head which may occur from a morbid state, or may be produced by changes of position in the body. Such are vertigo, a sense of fullness, or of a weight in the head, a feeling of a tight cord round the head. These are, no doubt, truly subjective, arising from altered states in the distribution or in the quality of the blood sent to the brain. A sensation of a rushing of blood to the head is often consequent upon excessive hemorrhage, or accompanies a state of extreme debility from any cause. This is, doubtless, owing in great part to the feeble tone of the arteries, resisting imperfectly the flow of blood to the head, and allowing it to impress the nervous matter too much. It is well known, that, by turning round quickly on one's own axis, the sense of vertigo may be produced; a confused feeling in the head, and an inability to maintain the balance of the body, accompanied by an appearance as if external objects were revolving. If the eyes be kept shut, the uneasy feeling of the head will take place, but no true vertigo. To obtain this feeling perfectly, the eyes must be open, and objects presented to them. And Purkinje has shewn that the direction in which external objects appear to revolve is influenced by the position of the body and of the head while turning round, and by the position of it afterwards, when the experimenter has ceased to move round. If the experimenter have kept his head in the vertical position while moving round, and afterwards when standing still, the objects appear to revolve in the horizontal direction. If the head be held with the occiput upwards while turning round, and then erect when standing still, the objects seem to rotate in a vertical plane, like a wheel placed vertically revolving round its axis.* It is highly probable that these sensations, as well as those which arise spontaneously, are due to some irregular distribution of blood to various parts of the brain. A sense of giddiness frequently precedes fainting, and is attributable to the temporary deficiency in the supply of blood to the head. If the horizontal position be immediately adopted, or the body be laid with the head inclined downwards, the faint may be prevented. The sense of giddiness which is experienced upon rising from the horizontal position after illness, is doubtless of the same kind. Anæmic patients experience this feeling of giddiness even in the horizontal position; and both it and the headache and delirium, which accompany this state of bloodlessness, may be relieved by placing the patient on an inclined plane with the head downwards.

The mind possesses a remarkable power of exciting and of exalting painful sensations in various parts of the body. If the attention be

* Müller's Physiology, by Baly, vol. i. p. 848.

directed very strongly, and for some time, to any part, it may become the seat of pain, for which the most effective remedy is to engage the thoughts as much as possible on some other object. In many instances, where pain has been excited by a physical cause, there can be no doubt it has been continued long after the cessation of its exciting cause, by the attention of the patient having been directed to it. It is probable, that in such cases the *perceiving* parts of the brain (so to speak) become habituated to a certain condition of the centre of sensation, produced by the original exciting cause of the pain. And, on the other hand, pain, at first excited by the mind, may be rendered permanent by habit; a certain physical alteration in some part of the centre of sensation being induced by the frequent repetition of the mental act in reference to a particular part of the body.

Those parts of the brain which are capable only of mental nervous actions, that is, of actions by which the mind is immediately affected, or which the mind can develope, have no nerves implanted in them. Such are the convolutions, the corpora striata, the optic thalami, and the cerebellum. The only apparent exceptions to this statement are the olfactory and optic nerves: these nerves, however, have in truth no immediate connection with any of the parts above mentioned. The former are implanted in the olfactory lobe; the latter in the chiasma, which is formed by the junction of the optic tracts, and these ought no more to be regarded as portions of the optic nerves, than the olfactory lobes should be considered as nerves.

Functions of the commissures.—The anatomy of the parts which we call commissures indicates that the name by which they have long been known is not misapplied, inasmuch as they seem to unite particular portions of the nervous centres with each other. The most obvious object of such an union would be to ensure the harmonious cooperation of the parts thus united. And this view of their function is strengthened by the fact that the principal commissures bear a direct ratio in point of developement to that of the parts they unite, and that, when these parts are absent or defective, the commissures are deficient or wholly wanting. Thus the corpus callosum and the hemispheres are developed together; the fornix and the hippocampi, the pons Varolii and the cerebellar hemispheres.

In Stilling's experiments on the spinal cord it was found that when division of that organ was made along the median plane, a stimulus applied to one leg caused only reflex actions of that leg, and not at all of the other side of the body. The power of transmitting organic change from one side of the cord to the other was destroyed by the section of the commissure.

The anatomy of the corpus callosum is favourable to the hypothesis that it is the bond of union to the convoluted surface of the hemispheres, and that it is in all probability the medium by which the double organic change is made to correspond with the working of a single mind.* There is nothing in the recorded observations of morbid change or congenital defect of this part to militate against this idea; but as all these cases are accompanied with lesion or defect of some other parts, and of the convolutions themselves, it is impossible to gather from them what is the precise consequence of the defect of the corpus callosum. This commissure is defective in the marsupiate class, as was shown by Professor Owen, and likewise in birds; but we have yet to learn whether there is any psychological character in either of these groups of animals, which would give us material assistance in our search into the nature of its function.†

Direct experiments upon the corpus callosum yield only negative results. Longet and others found that mechanical irritation of it did not cause convulsions; and Longet states that injury to the corpus callosum in young rabbits and dogs did not appear to disturb voluntary movements; and that when he incised this body in its whole length in rabbits standing, they continued to maintain that position, or, when urged on, ran; and that no convulsive movement whatever, nor any sign of pain, was manifested. Such effects are not unfavourable to the view above taken, as the connection of the centres of intellectual action is probably in no degree necessary to locomotion, which function would no doubt be as well performed without a corpus callosum as with one.

The fibres of the fornix manifest the same insensibility to mechanical irritants, and their obvious anatomical connection with particular convolutions warrants but one conclusion, that they associate the actions of those parts. The connection of this commissure with the optic thalami and the corpora mamillaria indicates that it also associates these gangliform bodies with the convolutions at the posterior part of the brain, and with the hippocampi. A marked relation exists between these latter convolutions and the fornix; they bear, indeed, especially

* Mr. Solly and Mr. Grainger think that they can trace the fibres of the corpus callosum distinctly to the convoluted surface of the hemispheres. With the greatest respect for these able anatomists, I must express my doubts that all the fibres which they have represented can be regarded as fibres of the corpus callosum. See fig. 99 in Mr. Solly's work on the Brain, p. 251, ed. 1847. Although the anatomical views of these writers correspond with and confirm the physiology of the organ advocated in the text, I feel that great caution should be used in drawing conclusions from tracing the fibres of brains *hardened* in alcohol. By these means any speculative anatomist may make preparations to illustrate his views, as is, indeed, abundantly shown by what I must call the fanciful anatomy of the brain put forward by Foville.

† An excellent account is given by Mr. Paget of a case in which the corpus callosum and fornix were imperfect, in the xxixth vol. of the Med. Chir. Trans., accompanied by some very judicious remarks upon the office of those commissures, and an analysis of other similar cases. Mr. Paget refers to some oblique fibres as existing in the corpus callosum, and serving to connect the anterior convolutions of one hemisphere with the posterior ones of the other.

as regards the posterior pillars of the fornix, a direct ratio to each other.

Lallemand relates a case in which the symptoms were altogether limited to mental disturbance, without any affection of the sensitive or motor powers, and the fornix and corpus callosum were found in a state of complete softening without discolouration.

The fibres of the pons Varolii bring the cerebellar hemispheres into connection with each other, and with the vesicular matter of the mesocephale. Direct experiments on these fibres can yield no satisfactory result, because they are so intimately associated with the deeper seated parts of the mesocephale, and with the nerves of the fifth pair and others, that it is impossible to irritate them in the living animal without affecting these parts likewise. The anatomy of the fibres, however, sufficiently indicates that they belong properly to a double cerebellum: for when the cerebellum becomes single, as in birds, reptiles, and fishes, no such fibres are found in the encephalon. Morbid lesion of the pons is productive of very serious results from the number and importance of the parts in its neighbourhood, the pyramids, the medulla oblongata, the quadrigeminal tubercles; so that the symptoms it produces cannot be referred solely to the injury to the commissural fibres. It is very probable, however, that the crossed effect of deep-seated disease of either hemisphere of the cerebellum may be accounted for by the influence of these commissural fibres upon the adjacent anterior pyramids, which again would influence the opposite side of the spinal cord.

Having thus brought to a termination our review of the physiology of the encephalon, I may now sum up the principal conclusions which our examination of this difficult and important subject leads to; and these are embraced in the following propositions.

1. That the encephalon consists of a series of centres, each of which has its proper influence in the exercise of the mental and bodily functions. These are the centre of intellectual actions, the centre of volition, the centre of sensation, the centre of the coordination of muscular movements, the centre of emotion, and the centre of respiration and of deglutition.

2. That the cerebral convolutions, with the fibres which connect them to the corpora striata and optic thalami, constitute the centre of *intellectual action.*

3. That the centre of *volition* consists primarily of the corpora striata; the inferior layers of the crura cerebri, which are continuous with the anterior pyramids, connect these gangliform bodies with the vesicular matter of the crura (locus niger), with the vesicular matter of the mesocephale, medulla oblongata, and with that of the spinal cord (the anterior horns), all of which with the corpora striata probably form the dynamic nervous matter in the impulses of volition for nerves implanted in them respectively.

4. The optic thalami, which by the extension of the olivary columns through the mesocephale and medulla oblongata to the posterior horns of the vesicular matter of the spinal cord, become continuous with those parts, constitute the centre *of sensation*, having implanted in it or connected with it less directly all the sentient nerves of the body.

The nerves of the higher senses probably have each special ganglia or centres, which, however, are connected with the general centre; as the olfactory lobes for smell; the retina, corpora geniculata, or corpora quadrigemina for vision; the vesicular matter in which the auditory nerves are implanted or the flocks of Reil for hearing; the ganglia of the fifth, glosso-pharyngeal, and posterior roots of spinal nerves for taste and touch.

5. The cerebellum constitutes the centre of the coordination of muscular movements, both in locomotion and in all the complicated movements of the frame.

6. The upper and posterior part of the mesocephale, including probably the greatest portion of the corpora quadrigemina, constitutes a special centre of actions referable to the emotions, among which may be reckoned sexual impulses. This centre connects itself with the medulla oblongata by the olivary columns, and through the same channel with the posterior horns of the spinal vesicular matter.

7. The medulla oblongata constitutes the centre of respiration and deglutition, but it cannot be considered as wholly devoted to these functions, inasmuch as it consists likewise of continuations of the centres of volition, of sensation, and of emotion.*

Of the functions of the ganglions.—That ganglions are small nervous centres we are bound to believe, from the existence in them of a considerable quantity of vesicular matter mingled with fibrous matter. And the views which we have already expressed respecting the dynamic character of the vesicular matter warrant the assumption that wherever a special accumulation of that form of nervous matter is found, there must be a special source of nervous power.

* I have great pleasure in referring the reader to a very able essay on the physiology of the brain, (which I did not see until this article was at press,) in which very similar views to those expressed in the text are advocated, based on comparative anatomy. The author, who in justice to himself ought not to withhold his name, is evidently hampered by his adhesion to the excito-motory doctrines. I allude to the Review of Noble on the Brain in Dr. Forbes's Journal for October, 1846. I had already put forward similar opinions respecting the subdivision of the brain and the uses of its parts, in the section headed "*An hypothesis of the action of the brain,*" in the article NERVOUS CENTRES, published in 1845, and subsequently republished in a volume entitled "The physiological and descriptive Anatomy of the Brain, &c." chap. xii., and the same views were expressed in Mr. Bowman's and my "Physiological Anatomy and Physiology of Man," part ii. 1845, p. 291 and p. 374. I may add that the review to which I refer contains a very complete and masterly exposition of the weakness of the present system of phrenology.

There are certain facts connected with the larger nervous centres which strongly indicate the correctness of this assumption. Thus, the existence of special accumulations of vesicular matter connected with them, where any particular developement of the nervous force is needed, is much in favour of this view. As instances, we may cite the special electrical lobes in the electrical fishes, the ganglionic enlargements on the medulla oblongata of the gurnard, the median lobe, occupying a similar position to the electrical lobe above referred to, which is found in the remora or sucking-fish, and from which nerves are supplied to the suctorial disc on the head of that animal. Allied to these is the remarkable fact pointed out by Professor Sharpey, that the arms of the cuttle-fish contain ganglia which furnish nerves to the suckers which exist upon them in great number. Furthermore, the anatomy of the nervous system in some of the Mollusca, the Conchifera for example, in which a separate *ganglion* appears to exist for each function, for respiration, for locomotion, for deglutition, &c., is beautifully illustrative of the office of ganglia.

When, however, we come to inquire into the office of the particular ganglia which exist in Man and the Vertebrata, it is, in some instances, difficult to determine what object can be gained by a special evolution of nervous force by some of them. It may be inquired what is the function performed by the ganglia on the posterior roots of spinal nerves, on the large root of the fifth, on the glosso-pharyngeal, on the vagus nerves? Can it have reference, as already suggested in a former part of the article, to the part which these nerves perform in connection with tactile sensibility or with the sense of taste, as in the fifth and glosso-pharyngeal, in analogy with the ganglia attached to the olfactory and optic nerves, and probably with the auditory? Or have these ganglia anything to do with the nutrition of the parts among which their nerves are distributed, as Dr. M. Hall suggests, in which case they would present an obvious analogy, and might be classed with the sympathetic ganglia?

The data which would assist in coming to a right conclusion upon this subject are so few, that, with our present knowledge, it is impossible to form anything like a distinct hypothesis regarding it. I would remark with reference to the last-mentioned conjecture that it would receive great support if gelatinous nerve-fibres were found to take their rise from the ganglia and to follow the course of bloodvessels.

With regard to the use of the ganglia of the sympathetic, the proved existence of gelatinous fibres, peculiar to these ganglia and taking their rise from them, distinctly indicates that they are the seat of a special developement of nervous power, whether spontaneously arising in the nutrient changes of ganglia, or by the reflexion of a change propagated to them by afferent nerves implanted in them. The various facts which show that the sympathetic system enjoys an existence and power independent of the cerebro-spinal axis also confirm this view.

But we must enquire further what is gained by the passage of certain nerve-fibres through these ganglia, as is the case with most if not all the tubular fibres connected with them? It may be that in their passage through the ganglia the tubular fibres acquire an arrangement in new sets or fascicles in a manner analogous to that which occurs in the plexuses. But this can scarcely be the only object of this connection. Do these fibres associate the cerebro-spinal centres with the ganglionic system? or do they themselves in passing again through vesicular matter experience some modification in their vital endowments? These questions cannot be satisfactorily solved in the present state of our knowledge.

(This work contains a confirmation and extension of Savi's statement respecting the subdivision of the primitive fibres of the nerves in the electrical organ of the torpedo. Wagner shows that the subdivision takes place by the breaking up of one primitive fibre into numerous filaments, from each of which a network is formed among the elements of the electrical organ. He describes a somewhat similar arrangement of the nerves in muscles.)

(R. B. Todd.)

NINTH PAIR OF NERVES (*Nervi hypoglossi, vel gustatorii,* Winslow; *Lingualis,* Vic d'Azyr; *Ninth nerve* of Willis; *Twelfth* of Sœmmering.) The ninth pair of nerves take their origin from the side of the medulla oblongata, commencing by a variable number of small radicles in the fissure which separates the corpus olivare from the pyramidale.

The superior of these radicles are attached about the centre of this fissure, and the inferior a little below its termination; they are placed on a line one below the other, which line describes a slight curve looking upwards and backwards, following the curved form of the olivary body.

The origin of this nerve is superior to that of the first cervical, to which also it lies on a plane a little anterior; it is separated from the origins of the par vagum by the olivary body, and has lying immediately in front the corpus pyramidale and the vertebral artery.

The radicles which form the origin of this nerve vary in number from five to ten or twelve; and if any of these radicles be examined closely, they will be found to consist of two or more minor filaments, so that it is very difficult to say exactly by how many roots or origins the ninth nerve is attached to the medulla spinalis.*

These filaments in general unite into two fasciculi, which pass in a direction downwards, forwards, and outwards to the anterior condyloid foramen, through which the nerve escapes from the cavity of the cranium.

It rarely happens that these fasciculi unite in the cavity of the cranium; in general, they pass on separately until they reach the foramen, where in passing through the dura mater they become united into one trunk, which is here invested with a strong neurilemma, derived from the dura mater.

The ninth pair of nerves, on emerging from the anterior condyloid foramen, is in close relation to the eighth pair of nerves, the internal carotid artery, internal jugular vein, and with the superior cervical ganglion of the sympathetic.

Here the nerve lies external to the vagus. Connected to it by a dense cellular tissue, for a space about the eighth of an inch, it passes behind the internal carotid artery immediately before that vessel enters the carotid canal, and lies in front of the jugular vein; here also the nerve is connected to the anterior and superior part of the superior cervical ganglion, in a manner to be presently described.

In this situation the ninth nerve lies deep in the neck, being covered by the origins of the styloid muscles, the posterior belly of the digastric, the sterno-mastoid, the skin, platysma, and fascia.

The trunk of the nerve then passes downwards, outwards, and slightly forwards, escapes from beneath the posterior belly of the digastric and anterior edge of the sterno-mastoid, becomes more superficial, is crossed in this part of its course by the occipital artery, and at a point in the neck corresponding to the level of the third cervical vertebra,* and opposite the angle of the jaw,† the nerve turns forwards and upwards, forming an arch, the convexity of which looks downwards and backwards; here the nerve is covered only by the skin, platysma, and fascia, crosses and lies in front of the origin of the occipital artery, the internal jugular vein, external carotid artery, and vagus nerve; passing still inwards and upwards towards the posterior edge of the hyoglossus muscle, the nerve is crossed by the tendon of the digastric, lying here superior to the lingual artery.

It then passes between the mylo-hyoid and the hyo-glossus, and having reached the anterior edge of the last-named muscle, it enters and passes through the fibres of the genio-hyoglossus, in the substance of which muscle it divides into its terminating branches, the connections and distribution of which shall be examined after we have considered the connections of this nerve and the branches which it gives off and receives in its course through the neck.

The ninth nerve, on escaping from the anterior condyloid foramen, is connected to the par vagum, as was before noticed, by dense cellular tissue, but also by a nervous filament; further on, as the ninth nerve approaches the transverse process of the atlas, it receives a twig from the first cervical nerve, or from the nervous loop formed round the transverse process of the atlas by the communicating branches of the first and second cervical nerves.‡

In this situation, also, the ninth is connected by a small nerve with the superior cervical ganglion.

Ramus cervicalis descendens, seu descendens noni.—The next regular branch given off by this nerve is immediately before it turns in front of the jugular vein and carotid artery, when it gives off a large and regular branch called cervicalis descendens, or descendens noni.

The point at which the ninth nerve gives off this branch is immediately below the angle of the jaw, and where it escapes from under the edge of the sterno-mastoid muscle. The descendens noni from this passes downwards and forwards to the inferior part of the neck; at its origin this nerve frequently receives a twig from the par vagum; it passes down the neck in front of the jugular vein and carotid artery, crossing these vessels obliquely, being in this course superficial to the cellular investment derived from the cervical fascia which constitutes the sheath of these vessels.

Omo-hyoid branch.—About the centre of the neck, the cervicalis descendens gives off a considerable branch, which, passing in a direction upwards and inwards, enters the interior belly

* Quarum incertus numerus causa est, cura a variis varie descriptæ et delineatæ exstent. Alii enim quatuor, alii octo componi fasciculis dixerunt.—Sœmmering de Basi encephali et originibus nervorum, page 168.

* See Meckel, Manuel d'Anatomie, vol. iii. page 53.

† See Boyer, Traité d'Anatomie, vol. iii. p. 359.

‡ See Traité d'Anatomie, Boyer, vol. iii. p. 359.

of the omo-hyoid muscle, in the substance of which it ramifies.

Plexus.—Immediately below the tendon of the omo-hyoid, the descendens noni, uniting with branches given off by the second and third cervical nerves, forms a nervous arch, the convexity of which looks downwards and forwards. This plexus lies under cover of the sterno-mastoid, and in front of the jugular vein.

Sterno-hyoid and thyroid branches.—From the convexity of the arch formed by this plexus two or sometimes more nerves proceed downwards and inwards, and ramifying on the superficial surface of the sterno-hyoid and thyroid muscles, are distributed to them.

Cardiac branch.—Meckel states, that on the left side particularly he has been able to trace a branch from this plexus into the thorax along the pericardium as far as the heart. The cervicalis descendens is observed sometimes to vary from the above description, in its course down the neck, and in its relation to the great vessels; for, instead of lying anterior and external to the sheath, it is occasionally found to pass down within the sheath, and sometimes even behind it. I have also seen it pass for a short distance within the sheath in the upper part of its course, becoming superficial about the centre of the neck, and then running down in front of the sheath in the usual manner.

These varieties in the course and relations of this nerve are not, however, very commonly met with.

Thyro-hyoid branch.—The next branch given off by the ninth pair is where the nerve is passing under the tendon of the digastric, a little above the cornu of the os hyoides. Here it gives off a considerable branch named thyro-hyoid, from its distribution. This nerve passes from its origin downwards and inwards, crossing the lingual artery, to which it lies superficial, and is distributed to the thyro-hyoid muscle.

From the origin of the thyro-hyoid branch the ninth nerve passes inwards between the hyoglossus and mylo-hyoid muscles, and at the anterior edge of the hyoglossus it plunges into the genio-hyoglossus, in the substance of which its terminating branches ramify. In this course the ninth nerve supplies filaments to the mylo-hyoid, the hyoglossus, the genio-hyoid, genio-hyoglossus, and lingualis.

In the substance of the genio-hyoglossus the branches of the ninth nerve form distinct anastomoses with branches of the fifth (the gustatory); with this nerve the branches of the ninth form nervous loops or arches, the convexities of which look forwards, and from which branches pass off which may be traced to the mucous membrane of the tongue. There can be little doubt that these nerves are to be considered as compound, containing filaments derived both from the ninth and fifth pair. Most anatomists state, that the ultimate branches of the ninth can be traced no further than the structure of the muscles which enter into the formation of the tongue, and this appears to be true with respect to the branches which do not anastomose with the fifth pair; but it is more than probable, although difficult to demonstrate, that from the anastomosis spoken of above, a nerve, composed of filaments both of the ninth and fifth, proceeds, and is distributed to the mucous membrane of the tongue.

Comparative anatomy.—It has been asserted by Professor Mayer, that in the ox and some other Mammalia he has discovered a small posterior root to the ninth nerve, having on it a ganglion; to the investigation of this I have paid particular attention. I have repeatedly and with care sought for this posterior root and ganglion in the ox, and have never been able to satisfy myself as to the existence of a true posterior root to this nerve.

The anatomy, however, of this part in the ox is extremely interesting, and when examined may, perhaps, explain Mayer's opinion.

In the dissections which I have made of the ninth pair in the ox, the nerve was found to arise in the depression between the corpus olivare and pyramidale by several delicate roots, in a manner very similar to what is observed in the human subject; these roots uniformly formed two bundles, which perforated the dura mater separately, before doing which, however, the most inferior of these two bundles received a twig, which at first sight appeared to be given off by the spinal accessory; but, upon further and careful dissection, this twig was found not to come from the spinal accessory, but to arise by a number of distinct roots from the side of the medulla spinalis, anterior to the roots of the spinal accessory, in front of and distinct from which it passed up into the cranium, and joined the inferior of the two bundles, which formed the origins of the ninth, and uniting with this passed out through the anterior condyloid foramen.

When this nerve was cleansed, the pia mater and coagulated blood removed, which always loads these parts in the slaughtered ox, no enlargement or any thing resembling a ganglion could be discovered on its course. This nerve cannot be considered a posterior root to the ninth pair, for its origin from the medulla is anterior to that of the spinal accessory; and I am inclined to think that this nerve in the ox holds the same relation to the ninth that the spinal accessory does to the eighth. Can this be what Mayer supposes to be a posterior root to the ninth?

Winslow speaks of a communication between the spinal accessory and ninth nerve within the cranium, the existence of which in the human subject is described by Scarpa and Meckel;* I have never been able to trace any such communication in man.

On tracing the ninth nerve in the ox through the anterior condyloid canal, it was found to be united into one trunk, and enveloped with a strong neurilemma; nor could any ganglion be detected on the nerve in this part of its course.

In Birds, the ninth nerve is found to commu-

* See Manuel d'Anatomie, Meckel, vol. iii. p. 59.

nicate with the par vagum, to divide into two branches, one of which is distributed to the tongue and the other to the œsophagus. Müller states, that in the rattlesnake he has found this nerve escaping from the cranium by a special opening behind that for the eighth pair, with which it communicates, as also with the first cervical.*

In Fishes, the last cerebral nerve is described by Weber as arising by three roots, the posterior having a ganglion, and passing out of the cranium by a special foramen in the occipital bone, and being distributed to the pectoral fin.

From these circumstances Müller conceived that an analogy exists between the hypoglossal, or ninth nerve, and the spinal nerves, and says, " If we now take into consideration that the first spinal nerve in the human subject has sometimes only an anterior root, and that the hypoglossal in man has only an anterior root, but that in some mammalia (according to the hypothesis of Mayer) it has a posterior root also, it will be evident that the hypoglossal nerve belongs to the class of spinal nerves, and is as it were the first spinal nerve, which, however, generally passes out through a foramen in the cranium; this consideration renders the analogy between the last cerebral nerve in fishes and the hypoglossal nerve still greater."†

Physiology.—That the ninth pair is the nerve which influences the motions of the tongue is generally admitted, and that it deserves the name given to it of *motor linguæ* has been proved by the experiments of Mayo, Majendie, and Müller.

When in the living animal this nerve is exposed and excited by pinching or galvanism, violent spasms of the entire tongue are produced, and its division is followed by paralysis of that organ.

On this subject Mayo performed the following experiment. " I divided the ninth nerve on one side of the tongue in a dog; the animal did not seem much incommoded, but lapped up milk readily. I then divided the nerve on the opposite side; the animal appeared distressed, and did not again lap up the milk offered to it, though it smelt to it; and finally, when mustard was smeared on its nostrils, it made no use of its tongue to remove it, though evidently suffering from it."‡ Further, Mayo found that when the nerve was divided on both sides in a rabbit, and the tongue drawn out of the mouth, the animal had not the power of again retracting it.

A very interesting case is related by Montault and quoted by Müller, where a tumour pressing on the ninth nerve of the left side at its exit from the cranium produced an atrophy of this nerve; the symptoms were paralysis of the left side of the tongue with gradual wasting of the organ on that side; but the sense of taste was not in the least affected, being as perfect on the paralysed side as on the other.

We are warranted from these facts in considering the ninth nerve as that which influences the motions of the tongue in articulation and deglutition; but, besides directing the motions of the tongue, the ninth nerve influences the motions produced upon the os hyoides by the sterno-hyoid, sterno-thyroid, and thyro-hyoid muscles, which muscles receive branches, as before described, from the ninth and cervical plexus. The importance of this connection in action of these muscles with the tongue, in the performance of the functions of articulation and deglutition, is obvious; and in the turkey Müller has found a long branch going from this nerve to supply the muscles which in that bird shorten the trachea.

It is asserted that the ninth nerve, in addition to its motor influence, is also endowed with a certain degree of sensibility, and that, if the nerve be stretched or pinched in a living animal, there is evidence of the animal suffering pain; this has been tried on dogs and cats. Now if in these animals this nerve has a double origin, this would be easy to understand; but Mayer himself could not detach a posterior root in the cat; so that if this nerve, either in man or other animals, has any of the properties of a nerve of sensation, it is owing to the filaments which it receives from the cervical plexus. But the degree of sensibility communicated to the tongue through the influence of this nerve in this way must be very trifling; and it is now as well proved that the tactile sensibility of the tongue is owing principally to the influence of the gustatory branch of the fifth, as that the motions of that organ are directed by the influence of the ninth pair.

(G. Stokes.)

NOSE. (Human Anatomy.)—(Gr. ῥὶν; Lat. *Nasus;* German, *Nase;* French, *Nez;* Italian, *Naso;* Dutch, *Neus.)* The nose is the organ of the sense of smell, and a part of the apparatus of respiration and voice, and in accordance with the variety of its offices is complex both in form and in structure, many different tissues entering into its composition. The most simple method of describing its anatomy in man is the synthetical; I shall therefore give an account, first, of its skeleton, composed of bones and cartilages; and then, in succession, of each of the parts placed on the skeleton, and subservient to its several functions.

The *bones of the nose* are chiefly concerned in the formation of the internal deeply-seated part of the organ, that part which is called the nasal fossæ, *(cavæ nares,* or *nares internæ,)* or the cavities of the nose. These cavities are open widely anteriorly to the atmosphere, and posteriorly to the pharynx. The anterior aperture is, in the osseous skeleton, heartshaped, broader below than above, bounded below and on each side by the palatine and ascending processes of the superior maxillary bones, and above by the nasal bones. Its borders are, in the lower half, smoothly rounded; in the upper half, sharp and uneven. Below and in the middle line the anterior nasal spine projects forwards and upwards; and above it is the osseous septum, which divides the fossæ into two equal cr

* Elements of Physiology.

† See Elements of Physiology.

‡ See Mayo, Commentaries, part ii. p. 11.

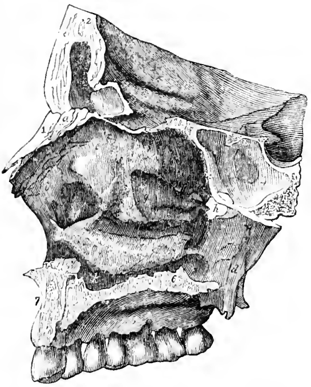
nearly equal portions, but of which the lower part alone reaches to the anterior aperture.

The posterior aperture of the nasal cavities is quadrilateral. It is bounded below by the palatine plates of the palate bones, with the posterior nasal spine formed at their junction; on each side by the internal pterygoid plate of the sphenoid bone; and above by the alæ of the vomer and the body of the sphenoid bone. The posterior edge of the vomer divides it into two equal lateral parts.

The space of which these are the apertures is altogether irregular in its form, but each of the halves into which it is divided by the septum may be described as having four walls or boundaries, a superior, inferior, and two lateral. The superior wall or vault of each cavity of the nose is formed in front by the posterior surface of the nasal bone; above and in the middle by the inferior surfaces of the nasal spine of the frontal, and of the cribriform plate of the ethmoid bone; behind by the anterior and inferior surfaces of the body of the sphenoid bone, and its turbinated bone, and by the ala of the vomer. The anterior part of this wall looks downwards and backwards, and presents shallow branched grooves in which branches of the internal nasal nerve lie, and one or more apertures through which one of those branches and an artery or two pass. The middle part of the wall is nearly horizontal, and is perforated by many apertures for the branches of the olfactory nerve, and for the internal nasal nerve; the posterior part looks downwards and forwards, and presents an aperture leading into the sphenoidal sinuses.

The lower wall or floor of the nasal cavity is nearly horizontal; it is concave transversely, a little raised at each end, and narrower before than behind. It is formed by the upper surfaces of the palatine plates of the superior maxillary and palate bones, and its inner border is a little prolonged both behind and before upon their nasal spines. Near its anterior border it is perforated by the superior orifice of the anterior palatine canal.

Fig. 399.



View of the outer wall of the nasal cavity on the right side.

1, nasal bone; 2, frontal bone; 3, frontal sinus; 4, sphenoidal sinus; 5, palatine surface of the hard palate; 6, edge of the palate bone; 7, anterior edge of the superior maxillary bone.

The outer wall is the most complicated. (*Fig.* 399.) If a vertical line be drawn downwards from the base of the nasal spine of the frontal bone (*a*), it will have in front of it the plain part of this wall, a slighty concave triangular surface, formed by the ascending process of the superior maxillary bone (*b*), and presenting nothing but some shallow grooves for bloodvessels and nerves. And, if a similar line be drawn downwards from the front of the body of the sphenoid bone (*c*), it will have behind it another plane surface formed by the internal pterygoid plate (*d*). Between these vertical lines there is a large quadrilateral surface divided into three parts by the three turbinated bones, whose edges project in nearly parallel and horizontal lines, at about equal distances one above the other. At the upper part of this surface and anteriorly is a thin quadrilateral plate (*e*) belonging to the cellular portion of the ethmoid bone, made very rough by grooves and apertures which lodge branches of the olfactory nerve. The anterior part of this plate forms the inner wall of the anterior ethmoidal cells; the posterior part (*f*) is a little curved outwards, and leaves a space between its surface and the body of the sphenoid bone into which the sphenoidal sinus opens. The lower border of this plate is continuous anteriorly with the inner surface of the middle turbinated bone, and posteriorly has a free margin which is slightly curled outwards. From the form of this margin the plate is called the superior turbinated bone, (*cornet supérieur; oberste Muschel;*) and the space which it here covers, and which is a kind of horizontal channel between its outer surface and the wall of the adjacent ethmoidal cells, is the *superior meatus* of the nose. Into this meatus the posterior ethmoidal cells open, usually by two or more orifices concealed by the turbinated bone; behind and a little below it is the spheno-palatine foramen (*h*), at which the nasal branches from the spheno-palatine ganglion and the spheno-palatine vessels enter the nose; and yet further backward, and nearly opposite the end of the superior turbinated bone, is the opening into the sphenoidal sinuses.

Below this upper plate, and continuous with it anteriorly, is the inner surface of the *middle turbinated bone* (*g*), another portion of the ethmoid bone, (*cornet moyen; mittlere Muschel.*) It is larger than the superior, more convex on its inner surface, and presents a free margin through the whole extent of its lower border, which is thick, and abruptly curled outwards, and sometimes has cavities within it (*sinuses of Santorini*), communicating with the ethmoidal cells. The inner surface of the bone is deeply grooved and perforated by bloodvessels and branches of the olfactory and naso-palatine nerves. Of the grooves, those which lodge the olfactory nerves run from above downwards, and those in which the naso-palatine nerves lie are directed forwards; at its lower margin also is a particular groove in which a large bloodvessel runs. The outer surface is concave and smoother than the inner, and forms the inner boundary of the *middle meatus* of the nose. On the outer wall of this meatus, which is a much larger channel than the superior one, extending through nearly the whole length of the outer wall of the nasal fossæ, there are presented from before backwards, after removing the turbinated bone,—1. a part of the ascending process of the upper jaw-bone; 2. part of the inner surface of the lachrymal bone; 3. the walls of some of the anterior ethmoidal cells; 4. the *infundibulum*, a long, narrow, and slightly curved passage, leading obliquely upwards and forwards into the anterior ethmoidal cells, and through them into the frontal sinuses; 5. the entrance into the antrum, a large aperture of uncertain size and form; and, lastly, a flat surface of the vertical plate of the palate bone.

Below the middle meatus is the *inferior turbinated bone*, the largest of the three, and usually described as a separate bone, because it is not so soon united to the adjacent bones. It is very uncertain in form and size; its depth especially varies; so that its lower border sometimes nearly touches the floor of the nasal cavity, and sometimes is half an inch above it; sometimes, also, it is so much curled outwards that it nearly forms a canal between its outer border and the outer wall. On the whole, however, this turbinated bone presents the same general characters as the others. Its upper margin is fixed to a prominent ridge along nearly the whole length of the outer wall of the nasal fossæ; its lower margin is free, and its outer surface forms the inner boundary of the *inferior meatus* of the nose, of which the outer boundary is formed by the ascending plates of the superior maxillary (*k*) and palate bones. At the anterior part of this meatus is the inferior orifice of the nasal canal, a passage flattened at its sides, larger at its extremities than in the middle, and passing, with a slight anterior curve, upwards, forwards, and a little outwards to the inner angle of the orbit. It lodges the nasal duct. At the level of this meatus also, behind the edge of the internal pterygoid plate, and about midway between the floor of the nose and the end of the inferior turbinated bone, is the opening of the Eustachian tube; but nothing of this is seen in the skeleton.

The inner wall of each cavity of the nose is formed by the *septum*, a median partition composed of the perpendicular plate of the ethmoid bone, and the vomer, whose edges correspond to ridges formed at the median sutures of the nasal, superior maxillary, and palate bones, and on the inferior surfaces of the frontal and sphenoid bones. The septum is not commonly quite vertical: it may lean to either side, or may be curved slightly in both directions, or may be convex on both sides and have a cavity in its interior. Each of its sides exhibits at the upper and back part the grooves of some of the olfactory nerves, becoming more shallow as they descend; and in various parts it is slightly marked by the passage of bloodvessels and other nerves.

Thus, the bones which form the proper cavities of the nose are fourteen; viz.—the two nasal, two superior maxillary, two palatine, the two inferior, and two sphenoidal turbinated, bones, the frontal, ethmoid, sphenoid, and vomer. And, with the space which these enclose, many adjacent cavities communicate; viz.—1. The frontal sinuses, which open through the anterior ethmoid cells and infundibulum into the middle meatus. 2. The anterior ethmoid cells, which open by the same canal or by separate apertures, into the same meatus. 3. The posterior ethmoidal cells, which open into the superior meatus. 4. The sphenoidal sinuses, which open through the posterior part of the roof of the nose behind the same meatus: and 5. The antrum, which opens into the middle meatus.

The osseous parts hitherto described form the skeleton of the interior of the nose, but contribute little to the formation of its external prominent part. Of this part the osseous skeleton is composed of the two nasal bones, and the nasal or ascending processes of the superior maxillary bones, which together form the *bridge* of the nose and a small portion of its lateral walls. Each nasal bone is elongated, quadrilateral, and narrower above than below. Its anterior surface is convex from side to side, and either presents a double curve from above downwards, or is slightly concave in its whole length. The two together form a prominent arch above and in front of the anterior aperture of the nose: their surface is continued outwards and downwards over the ascending processes of the superior maxillary bones, is smooth, and is marked only by small apertures giving passage to bloodvessels and nerves.

The internal edges of the nasal bones are united in the median line by a straight suture, the continuation of the sagittal suture. In front their union is smooth; but behind and above, where the bones are much thicker than they are below, a deep ridge or crest is formed which is received into that part of the septum of the nose which is formed by the nasal spine of the frontal bone, and the vertical plate of the ethmoid. Sometimes, however, these margins, instead of forming a ridge, are separate, and enclose a groove in which the edge of the septum is received. The superior thick borders of the nasal bones articulate by a serrated suture with the notch and the nasal spine of the frontal bone; and this suture, which forms part of the great transverse suture, is continued into that uniting the nasal processes of the superior maxillary bones with the internal angular processes of the frontal. The outer and largest margin of the nasal bone articulates with the nasal process of the superior maxillary, and is slightly overlapped by its sharp edge. The lower free margin is sharp and uneven.

The median suture of the nasal bones, and the short portion of the sagittal suture immediately above it, are the parts of the median suture of the skull which remain longest unossified: in ordinary cases, indeed, they do not close even in the latest periods of life. This, in some measure, distinguishes man from the other quadrumana: in the Chimpansé, the nasal bone is single; in the Orang, also, it usually is so; and in the adult Siamang (whose skull approaches nearest in form to that of man) and other Gibbons, the nasal bones are always united.* But a more distinctive character is the breadth and shortness of these bones in man, and the elevation of their inner borders, on which the projection of the upper part of the bridge of the nose depends; a projection in which the nose of the lowest negro surpasses that of either the Chimpansé or the Siamang.

The *structure of the bones* of the nose presents little that is peculiar. The thin lamellæ of the ethmoidal cells, the turbinated bones, and others of similar structure, receive their materials of nutrition entirely from the bloodvessels of the Schneiderian membrane. They contain no vascular canals within their own substance. Their corpuscles and minute canals which proceed from them are larger than those of average size: the former are very numerous and closely set, and the latter ramify in all directions; arrangements which seem to be adapted to the combination of the least possible weight with the necessary firmness of support.

Cartilages of the nose.—Of these, one completes the septum, and the rest form the skeleton of the lower and lateral portion of the external nose.

The cartilage of the septum (*septum mobile nasi*) (*fig.* 400) is the only one immediately connected with the bones. It occupies, in general, nearly the middle vertical plane of the nose; but, like the osseous septum, it often deviates to one or the other side, and has surfaces more or less curved. Its outline varies with the general shape of the nose, but is usually bounded by three unequally curved lines, of which the inferior is the longest, and the anterior and superior are of about equal length. Its superior border (*a, fig.* 400) is fixed in the whole length of the groove which usually exists in the lower margin of the perpendicular plate of the ethmoid bone: it is directed very obliquely backwards and downwards, and at its posterior extremity is conti-

Fig. 400.

The cartilages of the ala of the nose in situ.

nued with a curve into the lower border (*b*), of which a part fits in the same manner in the anterior margin of the vomer, while the remainder projects straightforwards in front of the anterior nasal spine, and forms the base and middle part of the *columna (sous-cloison,)* or partition between the apertures of the nostrils. Anteriorly, this lower border of the cartilaginous septum is continued with a curve which lies at the apex of the nose, into the anterior border (*c*). This last lies immediately beneath the skin, and, becoming gradually thicker, is continued upwards to the junction of the nasal bones, where the cartilage (at *d*) is thicker than at any other part.

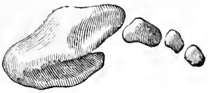
Of the lateral cartilages, two on each side are regularly found. The upper pair, (*a, fig.* 401,) which are named *superior, lateral,* or *triangular* cartilages, have each in general the form of a triangle with its angles rounded off. In front they are continuous, or very closely connected with the upper half of the anterior edge of the cartilage of the septum;* but each of them projects a little beyond it, so that it lies in a kind of groove between them; and, sometimes, each is prolonged downwards in a free sharp process by its side. Behind, they are closely attached by fibro-cellular tissue to the rough part of the free margins of the nasal and superior maxillary bones. Below, their margins are connected with the cartilages beneath them (*b, fig.* 401) by a tough but thin and pliant fibrous membrane, in which several small oval portions of cartilage are sometimes arranged in a row.

The *inferior cartilages* (*fig.* 402, and *b, fig.* 401) are also called *pinnal cartilages,* or *cartilages of the alæ,* because they form the basis of the more freely moveable lateral parts of the

* G. Vrolik, Recherches d'Anatomie Comparée sur le Chimpansé, p. 4.

* Hence Winslow, Bichat, and some others have described these as forming one *nasal cartilage* with the septum, and have divided the inferior cartilages into anterior and posterior portions.

Fig. 402.



Lateral view of the pinnal cartilages.

nose, and the *cartilages of the nostrils*, because they surround and in great measure determine the form of those apertures. The chief portion of each of them is nearly elliptical, and occupies the anterior part of the ala of the nose. Posteriorly, this portion either becomes suddenly narrower, and is continued in a long, undulating, and curved process through the middle part of the ala to the posterior and outer boundary of the nostril; or else it abruptly ceases, and, in place of the process, there is a row of three or more small oval portions of cartilage, *(sesamoid cartilages,)* imbedded in the fibrous membrane which forms the rest of the basis of the ala, and connects all the moveable cartilages to one another. Anteriorly, this chief elliptical portion is also continued into a narrow process, which, after proceeding for a very short distance forwards, turns round abruptly, and is directed backwards and a little downwards by the side of the lower margin of the cartilaginous septum, to which, as well as to its fellow on the opposite side, it is pretty closely connected by fibro-cellular tissue. In this course, the cartilage reaches a little beyond the anterior edge of the septum, so that, at the tip of most noses, there is in the middle line a small fossa bounded on each side by the lateral cartilages, and at the bottom of which is the anterior edge of the septum. The inner portion of this cartilage extends along about two-thirds of the inner boundary of the nostril, and terminates in an evenly rounded border; its lower margin is always rather lower than that of the cartilaginous septum, and assists in giving width and support to the columna. Sometimes, but more rarely, this inner process of the inferior cartilage is, like the posterior and outer process, separate from the chief elliptical portion.

The *structure of the cartilages* of the nose is essentially similar to that of the articular and other true cartilages, *(cartilagines figuratæ*, Meckauer.) Their cells are numerous, very close set and large; and next to each of their surfaces there are two or three layers of thin flattened cells, which give the borders of a section through the thickness of the cartilage a somewhat fibrous aspect. But the basis-substance is, in reality, entirely destitute of fibres.

The greater rigidity and firmness of the septum-cartilage is due to its greater thickness; its minute structure is similar to that of the cartilages of the alæ. The latter are easily flexible, but the pliancy of the sides of the nose does not depend on them alone, but in as great a degree on the tough fibro-cellular membrane in which they are imbedded. The combination of the two tissues is indeed admirably adapted to the purposes which are to be served. The cartilages are sufficiently rigid to give the alæ a definite form during rest; and they are so elastic that, when the nostrils have been either compressed or expanded, they are restored to their natural position by the recoil of the cartilages, without any muscular effort. If the whole side of the nose had been formed of cartilage, much stronger muscles would have been needed for the several movements of the nostrils; but, by the intervention of small portions of fibro-cellular membrane, these movements, whether rapid or long-sustained, are effected by some of the weakest muscles of the body, and with a scarcely perceptible effort of the will. The arrangement is somewhat analogous to that in which strength and flexibility are combined by strong scales or plates being set on the pliant substance of the skin of various animals.

The *muscles of the nose*, like those of the rest of the face, are but ill-defined, and anatomists have differed much in both the description and the enumeration of them. The following account is drawn from the results of several dissections purposely made, and compared with the descriptions of Santorini,* Arnold,† Theile,‡ and others, who have examined the matter for themselves.

Fig. 403.

Muscles of the nose.

* Observationes Anatomicæ, cap. i.
† Icones Anatomicæ, Fasc. II. tab. viii.
‡ Söemmering, Vom Baue des Menschlichen Korpers, Bd. iii.

1. *Pyramidalis*, (Casserius; *procerus*, Santorini; *fronto-nasal*, Chaussier.) This (*c, fig.* 403) cannot be strictly called a separate muscle of the nose, and it is described with the *frontalis* by Haller, Theile, and many others. It consists of those fibres of the median portion of the frontalis muscle which descend in a fasciculus over the upper part of the nose. They terminate in the cellular tissue covering the superior cartilage, and, through its medium, they are attached to the cartilage itself, and to the adjacent border of the nasal bone; many of them also are continued onwards and mingled with the upper fibres of the triangularis nasi (*e*), with whose aponeurosis, moreover, theirs is always continuous. At their inner margin these fasciculi are in contact above, but they diverge below as they pass over the surface of the nasal bones, and they thus assume that appearance of two distinct slender triangular slips of muscle which led Santorini to give them a distinct name, though they have not that distinct origin which he assigns to them.

The pyramidales do not appear to have the power of acting alone. When the rest of the frontalis contracts, and, by drawing down the scalp, wrinkles the skin of the forehead, they also act, raising and tightening the skin over the upper part of the bridge of the nose. They produce the same effect when the brows are drawn up, as in surprise.

2. *Levator labii superioris alæque nasi*, (Albinus, Weber, &c.; *pyramidalis*, Santorini; *oblique, ou lateral*, Winslow; *elevateur commun*, Bichat, Bourgery, &c.) This, (*d, d, fig.* 403,) which is the largest and strongest of the muscles of the nose, arises, internally, by a narrow slip of fibres from the upper and outer part of the ascending process of the superior maxillary bone, and, externally, by a broader origin from below the inner part of the lower border of the orbit. Its origins are covered by the orbicularis palpebrarum, and from them its fibres proceed downwards and diverge. About two-thirds of them pass to the outer part of the upper lip, mingling with the fibres of the orbicularis oris (*i*) and levator labii proprius, and inserted for the most part in the skin; the remainder go downwards and a little forwards over the posterior third of the ala of the nose. Of these last, some are attached more or less intimately to the posterior parts of the inferior cartilage and the membrane in which it is imbedded; many more terminate in the skin over the lower part of the ala, and are there mingled with fibres which run in various directions, but usually form a complete layer of muscular fasciculi beneath the skin of the outer border of the nostril.

In contracting, the nasal portion of this muscle draws up the ala of the nose, especially its posterior and lower half; and as the cartilage and other dense tissues of this part do not admit of wrinkling, the muscle, in its full action, turns the nostril outwards, and expands its aperture at the same time that it wrinkles the skin above it.

3. *Triangularis*, (Cloquet, Bourgery, &c.; *transversus*, Santorini, Winslow, Theile; *compressor nasi*, Albinus, Haller; *e, e, fig.* 403) is a thin pale muscle whose origin is covered by the preceding. It arises by a narrow aponeurosis from the upper and outer part of the canine fossa, behind and external to the base of the ala of the nose. Its fibres thence diverge, the lower ones passing almost horizontally, the upper ones forwards and inwards, and they form a thin triangular muscle which covers the upper part of the ala of the nose and reaches to the dorsum. Sometimes many of its fibres pass over the dorsum of the nose and mingle with those of the muscle of the opposite side; but more often there intervenes between the two muscles a pliant fibro-cellular expansion, into the borders of which many of their fibres are inserted, and which thus forms a kind of median aponeurosis extending over the front of the nose and enabling both the muscles to act at once and equally upon it and the ala. In general, also, the upper or outer fibres of this muscle are continuous with those of the pyramidalis or are fixed in its aponeurosis; and the lower fibres are mingled with fibres of the depressor alæ nasi, and pass into the irregular assemblage of fibres beneath the skin of the lower border of the ala. Many of the fibres are connected through their whole course more or less intimately with the other tissues of the ala and the skin; and probably it was from this last circumstance that Santorini was induced to describe this muscle as having the whole of its origin among the fibres of the levator labii superioris alæque nasi, or rather as a muscle peculiar for having its middle portion fixed (on the dorsum of the nose) and its two extremities moveable in the substance of each side of the upper lip.

These muscles have been described by some as compressors, by others as dilators of the nose, and in different circumstances they probably do act very differently. When the outer or maxillary insertion of each is fixed, they assist in compressing the nostrils, and in combination with the true depressors (presently to be described) their lower fibres draw the alæ backwards. When, on the other hand, they take their fixed point in the median aponeurosis on the dorsum of the nose, and contract towards it, those of their fibres which are connected with the skin will wrinkle it, as in the act of sneering, and those which are attached to the deeper tissues of the ala will draw it upwards and in some degree expand the nostril. When they compress the nostrils they commonly also draw backwards the apex of the nose in the manner usually seen in the act of smelling carefully.

4. *Depressor alæ nasi*, (Haller, Albinus, Theile; *Myrtiformis, seu pinnæ dilatator*, Santorini; *Petit dilatateur de l'aile du nez*, Bourgery; *incisif mitoyen*, Winslow; *dilatator narium*, Arnold; *f, fig.* 403) arises by short aponeurotic fibres from the alveolar margin above the second incisor and canine teeth of the upper jaw, below and on the inner side of the origin of the triangularis. Its fibres proceed upwards, forwards, and inwards, some going to the posterior part of the skin under the sides of the

septum, and many more to that of the alæ; many of them, also, first rising and then descending, form arches which are continued over the outer and posterior margin of the nostril, and are mingled with the fibres of the two preceding muscles, where they meet in the skin covering that part.

These muscles draw back and flatten the nostrils. Some of their fibres are mingled with those of the depressor labii superioris, or superior incisive muscle, and, whenever they act, the upper lip is fixed and somewhat elongated.

5. *Depressor septi narium*, or *nasalis labii superioris*, (Haller, Albinus; *naso-labial*, Bourgery; *k*, *fig.* 403;) may be regarded as a part of the upper portion of the circumference of the orbicularis oris, from which several fibres proceed forwards and inwards, converging from each side towards the septum of the nose. They are attached to the fibro-cellular tissue at the posterior borders of the nostrils, and the middle fibres pass forwards under the septum between it and the skin of the columna, many of them extending nearly to the tip of the nose.

When the rest of the orbicularis is fixed, this portion will draw the columna and the apex of the nose backwards and downwards; and when the rest of the orbicularis is relaxed, it will draw the middle of the upper lip upwards.

6. I have mentioned a layer of pale muscular fibres arranged in various directions under the skin of the lower part of the ala nasi, among which fibres of the compressor, depressor, and levator alæ nasi appear to mingle. It is by these fibres that the dilatation of the nostril is commonly effected; for, as any one may feel and see in his own person, this act is not usually performed by any of the muscles yet described, but by fibres which are situated below the triangularis and entirely within the moveable part of the ala. In most instances, no definite arrangement of these fibres can be perceived; yet they certainly sometimes form distinct fasciculi, which may be described as separate muscles. Arnold makes from them two muscles: 1. *Compressor narium minor*, (*g*, *fig.* 403), a small triangular muscle passing from the skin of the tip of the nose backwards and a little upwards, with its fibres diverging, to the anterior part of the inferior cartilage. Theile has never seen this muscle; in one very muscular subject I found a distinct trace of it; and it nearly corresponds to that which Santorini has drawn, (tab. i. *e*, *e*) and which he says he once saw in action during dyspnœa in a woman. He regarded it as a dilator of the anterior part of the pinna; Arnold considers it a compressor; the former opinion is the more probable. 2. Arnold has figured a larger quadrilateral muscle, *levator alæ nasi proprius* (*h*, *fig.* 403), which is nearly the same as Theile's *dilatator narium anterior*. Theile describes it as arising from the upper edge and outer surface of the inferior cartilage, its origin extending from within two lines of the dorsum of the nose to the sesamoid cartilages. Hence its fibres proceed downwards and are lost in the skin on the anterior part of the edge of the nostril. Its action is to draw the anterior part of the ala outwards, and thus to dilate the nostril. Theile also describes a *dilatator narium posterior*, which may be found by removing all the fibres of the common levator, the depressor alæ nasi and the triangularis. A mass of cellular tissue is thus exposed on the inferior and posterior part of the ala, in which muscular fibres may always be seen with the microscope, if not with the naked eye. They arise tendinous from the edge of the ascending process of the superior maxillary bone and from the sesamoid cartilages, and thence descending are lost in the skin of the posterior half of the edge of the nostril. Their action is to draw the posterior part of the ala outwards, and thus to dilate the nostril.

7. One more muscle may be mentioned, though it is only indirectly connected with the nose. It is that named *rhomboideus* by Santorini (tab. i. *f*), and *anomalus* by Albinus, from its being fixed at both its ends to immovable points. Its origin is confounded with that of the triangularis at the upper and outer part of the canine fossa; whence its fibres proceed in a broad fasciculus upwards and inwards in the fossa by the side of the nose to be attached to the surface of the superior maxillary bone close to the outer origin of the levator communis. The strength of the fibres of this singular muscle indicates that they must act frequently; but the only effect which their contraction can be supposed to have is that of tightening and drawing in the tissues over them with which they are pretty closely connected.

The purposes served by the muscles of the nose are but few. Their action contributes little to the various expressions of the condition of the mind. The sneer of contempt is perhaps the only expression in which they take a chief part. In extreme fear they appear also to be all contracted; but in this they are affected in common with the other muscles of the face, which all seem to be seized by a temporary spasm. Their other acts have reference to respiration, and are observed in their extreme degrees, in the dilatation of the nostrils to permit the freer ingress of the air in dyspnœa, and in their contraction in the endeavour to perceive a slight odour, by drawing the air quickly upwards towards the seat of the most numerous filaments of the olfactory nerve.

Integuments of the nose.—In their general characters these resemble the skin and mucous membrane of other parts: their peculiarities alone therefore need be here described.

The *skin* of the nose is smooth and fine, its papillæ being small and its cuticle very thin. It is soft, also, and pliant, and usually abundantly furnished with the sebaceous secretion. The hairs growing in it are numerous and exceedingly fine, so that many have denied their existence; the largest and most closely set are at the lower part of the alæ. The follicles enclosing them are deep and narrow; the conical pulps long and slender. The sebaceous glands are narrow and elongated; they lie near the sides of the follicles, have very short ducts, and are placed at but a little distance below the surface of the skin. Their secretion is copious, so that after death a mass of sebaceous matter may be squeezed from the orifice of each hair-follicle; and their ducts as well as the follicles themselves are said to be especially liable to be infested by the *acarus folliculorum* lately discovered by Dr. Simon.* I find none of the simple utricular follicles described by Cloquet and others in the skin of the nose; probably they were empty hair follicles.

On the upper three-fourths of the nose, the skin moves freely on the subjacent bones and cartilages, a thin layer of pliant cellular and adipose tissue being placed between them. In the lower fourth, and especially about the base of the nose, the skin is thicker and more compact than it is above; there is very little fat beneath it, and what there is is arranged in small and discrete granules; and the cutis, muscle, and fibrous membrane are so closely connected that they are moved together as one mass.

At the nostrils the skin of the nose turns inwards and is continuous with the mucous membrane, which, after lining the nasal fossæ and the cavities opening into them, is continued into the pharynx through the posterior nares, and into the nasal duct and Eustachian tube. The boundary between the skin and mucous membrane cannot be strictly drawn. It may be fixed, however, at the part just below which those hairs are implanted which converge from the inner circumference towards the centre of the nostril, so as to entangle any light body floating in the inspired air. These hairs are of the kind named *vibrissæ*. Like the eyelashes they are short, stiff, slightly curved, and pointed at their free extremities; and they are peculiarly well adapted for examining the minute structure of hair. In them also, as well as in the eye-lashes, one may best see the mode in which hairs are shed. In all which fall off spontaneously, or which, being about to fall, may be pulled away without pain, the conical cavity at the lower end, into which the vascular pulp fitted, is closed, having gradually contracted and shifted itself off the pulp as the hair ceased to be nourished and died.

The follicles of these hairs are similar to those of the hairs of the external integument, and each of them is associated with sebaceous glands, which, like those accompanying the hairs about the orifice of the vagina, are more numerous than in parts less exposed to the contact of fluids. A whorl of four or more small glands is often associated with a single hair-follicle; and when the hairs fall off, and their follicles partially close, the glands open, as if directly, by a common duct upon the surface.

The *mucous membrane* (Schneiderian or pituitary membrane) of the nose is far from uniform in its different parts. It is everywhere, and in some parts inseparably, connected with the periosteum or perichondrium which immediately covers the bones and cartilages, and which is often spoken of as the internal or deep layer of the *fibro-mucous* membrane; but, while the latter is in all parts nearly similar, differing only in thickness and degree of vascularity, the mucous membrane itself presents considerable diversities.

In the antrum and other supplemental cavities of the nose the mucous membrane is thin, but little vascular, and of the simplest kind, having neither papillæ nor glands embedded in it. On the turbinated bones, the septum, and the floor of the nostrils, it is thick, spongy, red, and turgid with blood collected in the plexus of large vessels in its areolar tissue. These vessels seem to form in some parts a distinct layer between the periosteum and the proper mucous membrane, but they are exactly analogous to those of the areolar or submucous tissue of other compound mucous membranes, in all of which there is a plane of large vessels from which those of smaller size ascend to the apparatus disposed upon the surface. In the Schneiderian membrane the veins of this plexus far exceed the arteries in size, and their close connection with the veins within the skull may be a provision for relieving the latter when subjected to an undue pressure of blood. The epistaxis of plethoric persons and of those who read hard probably has its origin in this connection; for the pressure of the blood in the congested cerebral vessels being communicated to the walls of these of the mucous membrane, these will burst more readily than those which are on every side supported by scarcely yielding tissues. The size of these veins, too, and the facility with which they permit distension, (almost resembling in this the veins of an erectile tissue,) account for the rapidity with which the membrane sometimes swells up, so as in a minute or two to obstruct the passage of the nose.

The free surface of that portion of the mucous membrane which lines the proper cavities of the nose is smooth. It presents the orifices of many simple follicles or crypts. They are most numerous about the lower and anterior parts of the walls of the fossæ, are of various sizes, and in many places lie in groups or rows. The follicles themselves are hemispherical, or deep and more or less elongated. At the lower and anterior part of the septum, there is often a single long duct running horizontally and leading to a collection of gland-cells which all appear to open into it; and, generally, some others of the larger orifices are connected with composite glands.

The *epithelium* of the nose is, in part, of the laminated, in part of the ciliary, kind. Henle* says that if an imaginary plane section of the nose be made from the anterior free border of the nasal bones to the anterior nasal spine of the superior maxillary bones, all the mucous membrane below and in front of this plane is covered by laminated epithelium, and all above and behind it by ciliary epithelium. The latter covers not only all the walls of the nasal fossæ, but is continued from them to the surface of

* Müller's Archiv. 1842, p. 218.

* Allgemeine Anatomie, p. 246.

the mucous membrane lining all the supplemental cavities, the nasal duct and lacrymal sac, and the upper part of the pharynx.

The *course* (as it is called) of the mucous membrane next merits consideration. Ascending from the floor of the nasal fossa up the outer side of the inferior meatus, it becomes gradually thicker and more spongy. From this meatus it is continued anteriorly into the nasal duct, around whose lower orifice it forms an annular fold or reduplication. The orifice in the bones is elliptical and rather obliquely placed, its anterior edge being somewhat lower than the posterior. The fold of mucous membrane around it is especially deep on the inner side and posteriorly, and not only contracts the size of the orifice, but acts as a valve to guard it, and, when pressed upwards and forwards, to close it. Hence, though some persons can inflate their lachrymal sacs, in most men, when the nostrils are closed, and air is pressed forcibly into the nose from behind, none ever escapes from its cavities.

As the lining membrane descends again upon the outer surface of the inferior turbinated bone, it becomes thicker, more spongy, and more vascular. At the lower edge of the bone it forms a deep fold, which, in its congested state, touches the floor of the cavity. The fold is peculiarly thick at the two ends of the bone, and in disease in scrofulous children it sometimes forms a loose and very vascular spongy mass, which has been mistaken, it is said, for a polypus. Immediately behind the deep posterior fold the membrane becomes again thin and adheres closely to the pterygoid plate of the sphenoid bone, behind which, and on a level with the extremity of the inferior turbinated bone, it is continued into the orifice of the Eustachian tube.

As it passes from the inferior turbinated bone to the outer wall of the middle meatus, the Schneiderian membrane becomes again thinner and more compact. About the middle of this meatus it enters the deep channel of the infundibulum, whose form it scarcely alters, and along which it passes to the anterior ethmoidal cells, and through them to the frontal sinuses. Above the commencement of the infundibulum it enters into the antrum by a narrow orifice directed obliquely from before backwards. Of the great opening into the antrum when the superior maxillary bone is separated, a large portion is covered by the palatine and turbinated bones; and of what remains, all but a narrow circular orifice at the upper and anterior part is closed by a thick annular fold of the mucous membrane; and even permanent closure is no rare consequence of the swelling to which the membrane is subject. Cloquet* says that this fold contains in man a gland with numerous orifices analogous to one of large size which surrounds the orifice of the antrum in many animals. I have not been able to find such a structure, and even E. H. Weber† has not been more successful.

The membrane covering the middle turbinated bone and the anterior portion of the cellular part of the ethmoid is thick and spongy, but less so than that on the inferior turbinated bone. In the superior meatus it is thin; and it becomes still thinner as it passes into the one or more orifices of the posterior ethmoidal cells, on the borders of which it is tightly applied, and whose size, as it forms no loose projecting fold, it diminishes but little. It closes, at this part, the spheno-palatine foramen, and in the vault of the nasal fossæ all the foramina of the cribriform plate, through which nerves and vessels are admitted to the outer surface of the mucous membrane, and the inner surface of the periosteum. At the lower borders of the superior and middle turbinated bones it forms thick folds, which make the meatus appear far smaller than they do in the dry bones. These folds are not so deep as that on the inferior turbinated bone; but, as they probably receive many filaments of the olfactory nerve, both they, and perhaps the inferior fold also, may be regarded as means for the multiplication of the sensitive surface, and as analogous, in some measure, to the folds of mucous membrane by which alone in Fish and the Proteus anguinus the same object is attained

In all the rest of its extent over the septum, the nasal bones, and the lateral cartilages, the Schneiderian membrane has a uniform surface and is of about middle thickness: its layers are intimately united, and it adheres with moderate firmness to the bone and cartilage.

Nerves of the nose.—The olfactory nerve, or, as it may be more properly called, *the olfactory lobe of the brain*, arises from the posterior, inner, and inferior part of the anterior lobe of the cerebrum. It lies in the groove between the two most internal of the convolutions of this part of the brain, and may be divided into three parts;—the posterior, or *pyramid*, the anterior, or *bulb*, and the middle, or proper *trunk* of the nerve or lobe. At its origin it may be traced backwards into three roots. Of these, the *outer* or *long root* appears first in the fissura Sylvii at the junction of the anterior and middle lobes of the cerebrum, just above the trunk of the middle cerebral artery. Hence, its chief portion proceeds inwards, forwards, and a little downwards on the under surface of the anterior lobe and in front of the *substantia perforata antica;* and on coming near the other roots it turns more directly forwards and unites with them at the beginning of the groove between the two convolutions. In this course it receives on its outer border one or more separate fasciculi, which come from the deeper part of the lobe and are sometimes completely concealed by grey matter covering them.

The *inner* or *short root* is first visible at the inner and posterior part of the anterior lobe of the cerebrum, in front of the beginning of the fissura Sylvii, and just outside the great median division of the cerebrum. It consists of one or more fasciculi, and passes outwards and forwards to the commencement of the groove, where, curving round like the preceding, but

* Osphresiologie, p. 247.
† Hildebrandt's Anatomie, Bd. iv.

in the opposite direction, it joins the other roots to form part of the pyramid.

The *middle root** arises between the two preceding roots, and first appears in two or three bands of fibres just in front of the substantia perforata antica, whence they proceed forwards to join the other roots.

Each of these roots is connected with grey matter prolonged from the surface of the anterior lobe and the fissura Sylvii, and especially from two slight elevations, one of which lies in the concavity of the internal, the other in that of the external, root, as they severally turn forwards where they join the middle root. The grey matter connected with the external root covers part of its origin, is continued along both its sides, and conceals more or less the filaments which join its outer border. Then connecting itself with the grey matter around the fibres of the middle root, they pass forwards together, and are lost near the apex of the pyramid; part of them entering its substance, but a greater portion forming a thin layer *(propago cinerea externa)* which covers its surfaces, especially the upper one. The grey matter connected with the inner root conceals many of the fasciculi of its origin, and two streaks proceed from it, of which one passes into the interior of the pyramid, separating the internal and middle roots, and the other, of much larger size, is continued over its surface. This latter is the middle or grey root of Cloquet, &c. (the *propago cinerea interna.)* It has a somewhat pyramidal form, and covers a part of both surfaces of the pyramid, but chiefly the upper surface. Its deepest edge penetrates to the middle root, and its outer edge sometimes joins the superficial layer covering the other roots. As it proceeds forwards it becomes more and more slender; and it is prolonged further on the upper than on the lower surface of the pyramid, near the apex of which it ceases.

Thus, the pyramid of the olfactory nerve is formed by three fasciculi of white filaments, separated by streaks of grey matter, by which also it is covered on both its borders and on a great part of its upper surface. It is between two and a half and three lines long; its base lies in the angle where the two internal convolutions of the anterior lobe diverge; and at its anterior extremity, becoming gradually smaller and flatter, it is continued into that which may be called the trunk of the nerve, the *tractus olfactorius.* This is nearly flat: it is grooved along the middle of its under surface, which rests on the upper part of the body of the sphenoid bone, and has a ridge, or is altogether convex upon its upper surface, which lies in the groove between the convolutions. It is striated in its whole length, and nearly white; though some grey matter is collected within the meshes of the plexuses, which its fibres form as they proceed forwards and a little inwards towards the bulb in which they expand. After long immersion in spirit, the groove on the under surface of the trunk, which, in the recent state, varies much in depth in different persons, always becomes deeper and more distinct. Valentin* suggests that it indicates the course of the canal which in the human embryo passed from the lateral ventricle to the end of the olfactory bulb. The analogue of this canal is persistent in the olfactory nerves of lower Mammalia; but there is no sufficient evidence of its having been ever seen in the human adult; at least in this part of the nerve.†

The bulb of the olfactory nerve is a nearly elliptical flat body, about half an inch long, slightly furrowed above, convex on its lower surface, and evenly rounded in front. It rests upon the dura mater covering the cribriform plate; its inner margin is in contact with that covering the crista galli, and with the anterior part of the falx cerebri; by which alone it is separated from the bulb of the opposite side. It is of a greyish-red colour from the quantity of grey nervous matter which is placed upon its surface and among the plexuses formed by the nervous filaments within it. In its interior a small cavity or ventricle may be generally detected by a vertical antero-posterior section: it is the remains of the embryonic condition just alluded to.

From the lower surface of the bulb proceed the numerous branches of the olfactory nerve. They vary much in number and size both in different persons, and on the two sides of the same individual; a want of symmetry which may often be seen in the perforations of the cribriform plate. The ordinary number of branches is from fifteen to twenty on each side. Each of them, invested by a very delicate neurilema, passes through an aperture in the cribriform plate, through which also a tubular prolongation of the dura mater passes and becomes continuous with the periosteum of the nasal fossæ. The nerves, which become rather firmer when they have passed through the cribriform plate, ramify between the periosteum and the mucous membrane, and are divisible into two chief sets, some being placed upon the septum, others upon the outer wall of the nose.

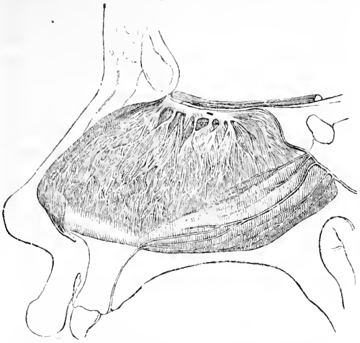
The internal or *septual* branches are about twelve in number. After passing through the cribriform plate, they diverge a little as they descend; the anterior going somewhat forwards, the posterior backwards. The trunks soon, and often while within the foramina of the cribriform plate, break up into tufts of filaments, which unite into plexuses with long and narrow quadrilateral meshes; and from these, smaller

* Confusion has arisen in the use of this name. The root here meant is that called *middle root* by Soemmering, Sir C. Bell, Mr. Swan, and Valentin. Weber and Hildebrandt, and Cloquet call that *middle* or *grey root* which lies above the others, and forms a thin grey band on the upper surface of the nerve: and under the *internal root* they include, as Haller and others did, who described only two roots, both the internal and middle ones. The names here adopted are preferable, because the white fasciculi alone could properly be regarded as roots of a nerve, they alone being continued to the branches, and because their arrangement is more constant than that of the grey matter.

* Soemmering, Vom Baue des Menschl. Körpers. Bd. iv. p. 299.

† See on this question Cloquet's Osphresiologie, and Metzger's Historia.

Fig. 404.



Branches of the olfactory and naso-palatine nerves on the septum of the nose.

branches proceed which again form finer plexuses. They may be traced nearly to the lower fourth of the septum.

The external or *labyrinthic* branches are rather more numerous and smaller. They diverge and ramify like the preceding, lying in the channels and grooves upon the upper two turbinated bones. They have been traced to the lower border of the middle turbinated bone, but not to its outer concave surface, nor to any part below it; yet the similarity of the structure and arrangement of the inferior turbinated bone and the mucous membrane over it makes it very probable that they ramify on it also. The middle branches are the longest; the posterior ones form curves directed backwards towards the sphenoidal sinuses, but not entering them. At the posterior angle of the middle turbinated bone some of them are described by Mr. Swan* and by Soemmering as anastomosing with a branch from the spheno-palatine ganglion; but Valentin † could not find any such communication. A few branches in addition to these are said to be distributed in the membrane covering the cribriform plate itself (Cloquet).

How the primitive filaments of the olfactory nerve terminate has not yet been ascertained; their softness and the density of the tissue in which they lie have hitherto prevented an accurate observation of them in this part of their course.

Compared with the other nerves the olfactory present many peculiarities of structure and arrangement, especially in the part which is within the skull. 1. They are the softest of the nerves within the skull, possessing only the most delicate neurilema; and a rather less degree of this softness is characteristic of their branches, so that their dissection is more difficult than that of any others of equal size. 2. They have grey nervous matter both upon and between their fasciculi, and their bulbs are not like the ganglions of other nerves, but like portions of the brain. 3. They are not, as other nerves, cylindrical, but triangular in one and flat in another part of their course. 4. Their trunks converge, while those of all others diverge from their origins. 5. They lie in deep furrows on the surface of the brain, and they leave the skull by several distinct orifices. In many of these characters they are more like portions of brain than nerves; and, as Valentin observes, there is no other nerve in the adult human body which shows its origin as an immediate prolongation of the central nervous mass so plainly as these do. It was on account of these characters that the olfactory nerves were regarded by the ancient anatomists as processes of the brain (mamillary or papillary processes), through the central canals in which they supposed that the pituitary humour was carried from the lateral ventricles to the nose, and air was drawn into them by the nostrils. And although this notion was derived from dissecting the nerves of animals in which the trunks remain hollow, yet their true nature was doubted on the same grounds by many, even after Willis had demonstrated their structure in man.*

In accordance with its numerous offices, the nose receives, in addition to these,—the nerves of its peculiar sense,—others for common sensation, for the movements of its muscles, and for the government, in some degree at least, of the organic processes which are carried on in it. Its sensitive and organic nerves are derived from the internal nasal or ethmoidal branch of the first or ophthalmic division of the fifth, from the naso-palatine and numerous other branches, from the spheno-palatine ganglion, the nasal branches of the Vidian, palatine, anterior dental, and infra-orbital nerves; all of which are described under the title FIFTH PAIR OF NERVES. Its motor nerves are supplied by the facial or seventh pair [SEVENTH PAIR OF NERVES].

Vessels of the nose.—Its arteries are derived from the ophthalmic, the internal maxillary, and the facial. The ophthalmic artery gives it the anterior ethmoidal, which enters with the ethmoidal nerve, the posterior ethmoidal, and the nasal, which anastomoses near the angle of the eye with the angular branch of the facial artery. From the internal maxillary trunk the nose and the adjacent cavities are supplied through many branches, namely, the alveolar, which sends branches into the antrum, the infra-orbitar, of which the terminal branches partly supply the skin, the Vidian, anterior palatine, pterygo-palatine, and spheno-palatine, each of which, as it passes towards or through the canal after which it is named, sends branches to the mucous membrane of the adjacent part of the nose or of the cavities opening into it. From the facial artery branches are derived both through the superior labial and from the trunk itself. Indeed, the dorsal arteries of the nose may generally be regarded as the termination

* Demonstrations of the Nerves, folio, p. 14, pl. xi. f. 3.

† Loc. c. p. 303.

* See Cloquet, and Metzger, l. c., and Sprengel, Histoire de la Médecine, iv. p. 69.

of the facial artery, for they are usually larger than the angular artery, which is given off as a branch from one of them. They chiefly supply the skin and muscles; they form a complete network over the nose, and those of one side anastomose freely in the middle line with those of the other. Many of their branches also pass between the cartilages or turn in at the nostrils and supply the anterior part of the mucous membrane.

The veins of the nose, so far as they are known, are associated with its arteries. Their communication with the veins within the skull has been already mentioned. The anastomosis is chiefly effected by means of the branches of the ethmoidal and spheno-palatine veins, which communicate with branches opening into the longitudinal and coronary sinuses.

The *lymphatic* vessels of the nose have not been particularly examined. Cloquet says their principal trunks accompany the blood-vessels and go to the jugular ganglia.

Developement of the nose.—The developement of the nasal cavities lays, as it were, the foundation for the construction of the face.* They are first formed as a kind of canal, whose lateral walls are chiefly composed by the anterior and lateral frontal processes of Reichert—those processes which grow out from the sides of the covering of the first cerebral vesicle *(Stirnkappe)*, in front of the first visceral arch. This canal has on its outer side and behind it the rudimental substance for the upper jaws, (the superior maxillary processes of Reichert,) and above it the base of the skull and the origins of the first pair of visceral arches thence arising. As the upper jaws grow with a rapidity far exceeding that of the growth of the frontal processes, they come at last to form alone the lateral walls of this canal, while the frontal processes form its inner walls; and, together with those changes, the canal becomes deeper, and its external apertures, which at first lay at the sides of the head between the two frontal processes of each side, approach the median line, and assume a lower position. After this, as the upper jaw of each side, continuing to grow inwards, approaches that of the opposite side, they at length unite to form the palate, and thus separate the common cavity, which at first existed, into an oral and a nasal cavity.

Of the parts just mentioned, the anterior frontal process is regarded by Reichert as the basis in which the nasal bone is developed; and the lateral frontal, or naso-frontal process as the basis for the lachrymal bone. The superior maxillary bone appears to be developed in the part named after it; the intermaxillary bone in a portion of the anterior frontal process, or its junction with the superior maxillary process; the palate bone and the pterygoid processes in the upper part of the first visceral arch.

The formation of the parts within the nasal cavities is, he says, thus effected: within the formative substance enclosed between the walls of the one rudimental cavity two cartilages form; one of these is the prolonged cartilaginous body of the first cephalic vertebra which forms the septum of the nasal cavities, and may be traced without any breach of continuity to their outer orifice, where it ends membranous in the adjacent formative mass. The other cartilage is double, and appears somewhat later than the preceding, on each side of which it lies close to the lower part of the first cephalic vertebra, with an arched surface directed outwards to the eye. Each of these second, or lateral cartilages becomes the cellular portion of the ethmoid bone, the *lamina papyracea*, and may be easily separated from the vertebra and its visceral arch, from which its formation is entirely distinct. Even for some time after they are ossified this separation may be effected without injury to the surrounding parts; but at a later period they completely coalesce. The ossification of the septum takes place later than that of the other bones of the face. In all Mammalia it makes progress from the base of the skull downwards and forwards, and in all a part of the septum in front and below is left unossified; so that divisions are produced which had originally no existence. The vomer, Reichert thinks, is formed separately when the palatine portions of the superior maxillary bones meet together.

The olfactory nerve is originally, like the optic and auditory nerves, a kind of vesicular or tubular prolongation from the medullary tube which constitutes the cerebro-spinal axis of the embryo. According to Valentin,* it proceeds from the most anterior part of this tube, that is, from the foremost of the three embryonic cerebral vesicles; but, according to Reichert, from the lower and front part of the side of the second of them. Von Baer† found the olfactory nerves presenting this vesicular form in the chick during the third day of incubation; they projected from the lower surface of each hemisphere into the formative tissue of the skull, and exhibited a small round pellucid surface bordered by a dark circle. Rathke observed similar appearances in the sheep and adder. The interior of the vesicle is lined, according to Valentin, by a delicate ciliary epithelium. Anteriorly it appears to terminate at the end of the olfactory bulb; posteriorly it is continuous with the anterior part of the lateral ventricles of the cerebrum.

The early developement of the human nose has not been particularly studied, but is probably very similar to that just described from observations in the lower animals. In a well-formed embryo an inch in length, I have found the nasal cavities of proportionally large size. On their lateral walls they present distinct traces of the rudiments of the two lower turbinated bones in prominent horizontal folds of the lining membrane. The palate is at this time formed only anteriorly and at its sides; its middle portion is widely open, exposing to the view from

* Reichert, Ueber die Visceral-bogen, Müller's Archiv. 1837, pp. 144 and 159. This account is drawn from the developement of the Pig.

* Soemmering, l. c. p. 404.

† Quoted in Bischoff, Entwickelungsgeschichte (Soemmering, Vom Baue, &c. B. viii.)

below the free inferior border of the septum. The upper edge of the septum is firmly fixed to the base of the skull, and its posterior edge gradually slopes back to the upper and back part of the wide cavity of the pharynx. There is no appearance of a vomer; and the nose does not project upon the face. Its position is marked externally by the nostrils, which are elongated vertically, oval and narrow, situated about three-fourths of a line from the margin of the upper lip and at the like distance from each other. They are not at this time closed, but lead straight backwards into the common nasal and oral cavity.

In the following periods the chief changes are effected by the gradual closure of the palate, the fixing of the lower margin of the septum, the developement of the vomer, and the growth of the anterior part of the septum and of the rudiments of the nasal and superior maxillary bones. With these changes the nose gradually becomes more prominent, and the nostrils, which at first look straightforwards, are gradually turned obliquely downwards, and at last are directed as in the adult nearly straight downwards. During the third and fourth months, according to Burdach, the nostrils are closed by a fine membrane, which in the fifth month is again removed. Together with the change in their direction already spoken of, the septum becomes narrower and the distance between them is diminished. Changes perfecting these are continued even long after birth in the gradual elevation and elongation of the bridge of the nose, and in the narrowing of its base; and it is in these changes subsequent to birth that noses, which present little variety in infants, acquire the almost infinite diversities of form by which they characterize the faces of adults.

Physiology of the nose.—Most of the purposes to which the nose is subservient in the economy are described in other articles. [SMELL, LARYNX, MUCUS, FACE.] Here, however, it may be considered as the first portion of the respiratory passage, and as a feature characteristic of the human race and of its several varieties.

The nose is the proper channel through which the air is drawn into and expelled from the lungs. It alone is habitually used in respiration by most animals, and though in man the mouth is as often used in breathing as the nose, (and, indeed, oftener in our own climate, in which, from various causes, few persons have at all times both the nasal passages free,) yet it is not adapted to this office so well as to be used long without inconvenience. Most persons must have suffered the discomfort of breathing through the mouth during a few hours' sleep: all its lining membrane, as well as that of the fauces and of the upper part of the larynx, becomes dry, and an excretion of saliva must be artificially produced before the annoyance and the danger of choking can be removed. No such inconvenience attends the breathing through the nose for any length of time. Its more extended mucous membrane supplies a fluid sufficient to keep its own epithelium moist, and to saturate with vapour the air which passes over it, so that this air does not abstract so much moisture from the surface of the epiglottis and the glottis as the drier air which has passed through the mouth alone.

Again, the nose is far better adapted than the mouth is for the arrest of the particles of foreign solid bodies which float in the air. If such particles have passed through the hairs which lie at the orifices of the nostrils, and which are sufficiently close-set to stop even very minute bodies, they are in their further course liable to be caught in the irregular surfaces of the walls of the nasal fossæ and entangled in the moisture of their lining membrane. Hence most persons can breathe through the nose for some time without inconvenience even in a cloud of dust: and the nasal cavities of the horse and other Mammalia are, in this respect, still better adapted for the protection of the lungs. Some experiments were performed in France to determine whether great injury of the respiratory passages of horses were produced by their exposure to the dust of roads. Horses were made to trot for a considerable distance in the clouds of dust thrown up by the wheels of carriages driven before them; they were killed directly afterwards, and not a particle of dust appeared, on the closest scrutiny, to have passed beyond their nasal fossæ.

The nose is further adapted to be the first portion of the respiratory passage by the acute and peculiar sensibility of its mucous membrane, and by the connection of its nerves in the nervous centres with the nerves of all the set of respiratory muscles. Through the olfactory nerve the nose detects the impurity of the air from those gases whose deleterious properties are indicated by odour; and its acute common sensibility affords a warning of the presence of any mechanical or other common irritant. The act of sneezing, which in this last case is excited through the already-mentioned connection of these nerves, is an example of that class of half-involuntary acts* which are consequent on acute sensations; and, in this respect, it is widely distinguished from the other reflex acts with which it is commonly classed, but which are never, or at least not necessarily, connected with sensation. Every one must have felt that a certain acute sensation is necessary in order that a sneeze should occur; and if the sensation does not arise to that certain degree of acuteness, the disposition to the sudden forcible expiration gradually passes off, though the act had been desired and had seemed on the point of being accomplished. In this respect sneezing is exactly analogous to coughing,—an act which is never thoroughly effected except in consequence of a certain acuteness of sensation at the glottis. And the analogy is maintained in this also,—that the cause of irritation which produces sneezing may be seated either in the nose itself, where it is always felt, or in another part. In cough-

* They may be thus called, because, though the sudden and simultaneous exertion of all the muscles concerned is involuntary, and almost inimitable, yet the putting them in a position for that exertion is always voluntary.

ing, the sensation which immediately precedes the act may be the consequence of direct irritation of the glottis, or of irritation of another part, such as the distant bronchial tubes, from which the impression is conveyed to the brain, and there, as it is supposed, is radiated to the central extremities of the nerves of the glottis, and is *felt* as if it were applied to their peripheral extremities. In either case the peculiar sensation at the glottis is the necessary precedent of the act of coughing; and it is the same in sneezing. A sudden vivid impression of light upon the retina, or, sometimes, the irritation of a tender point on the skin of the face, produces a sensation of pain or irritation in the mucous membrane of the nose, and sneezing follows. The sequence of events may be supposed to be,—an impression on the peripheral filaments of the retina,—its conveyance to their central extremities in the brain,—its radiation to the central extremities of the sensitive nerves of the nose, producing the same sensation as if their peripheral extremities had been irritated,—and, through that sensation, whether it be objective or subjective, the half involuntary act.

The great prominence of the external nose, and the comparative smallness of its internal cavities, form one of the most distinguishing characters of the human face. Cuvier has pointed out how the relative proportion in size between the cranium and the cavities of the nose and mouth affords an indication of the approach towards perfection of the internal and intellectual faculties in comparison with the external or sentient. For the senses of smell and taste " are those which act on animals with the most force, which most powerfully master them, through the energy which two of the most pressing desires, hunger and lust, communicate to their impressions."* But in man the sense of smell is, in both these regards, subordinate to that of sight; and the developement of his internal olfactory apparatus is, in comparison with that of lower animals, extremely small. In the varieties of the human race the perfection of the sense and the developement of its organ are the less the more civilized their several habits of life are. Among ourselves, the blind alone maintain the sense in the energy of which it is capable, and in which it is said to be habitually exerted in some less civilized tribes. In the latter a greater developement of the organ of smell, and even of its osseous part, corresponds with its greater acuteness and the degree in which it is exerted. The greater distance between the orbits, which is especially remarkable in the Kalmucks and other Mongolian tribes, may be an indication of this greater developement; but a more important one is the size and complexity of the turbinated bones. The nasal fossæ of the skulls of Negroes are larger in all their dimensions than those of Europeans; and Soemmering,† in numerous examinations, found the sinuses within the middle turbinated bones

* Leçons d'Anatomie Comparée, ii. 160.
† Ueber die Verschiedenheit des Negers.

constant in the Negro, though rare in others. Blumenbach* confirms both these observations, and mentions particularly the skull of a North-American Indian in his collection, in which these sinuses were of extraordinary size. However, these differences of size are probably not a full measure of the differences of acuteness of the sense: it is most likely that in the nose as in the other organs of sense, acuteness of perception is connected with fineness of division, rather than with extent of distribution, of the recipient nerve.

The prominence of the nose is even more characteristic of man than the smallness of its cavities. In other Mammalia it stands out, indeed, much further from the skull, but it is in company with the upper jaw, beyond which it does not, as in man, project. For the same reason, the nostrils, which in man are horizontal and directed downwards, in adaptation to his erect posture, and to his hand ever ready to carry objects to them, are, in the lower animals, vertical. The nasal processes of their superior maxillary bones, also, lying flat and being very broad, and the small size of their nasal bones, prevent the peculiarly human elevation of the bridge of the nose.

The forms of the external nose are among the characteristics of the varieties of our species. In all its almost infinite varieties of form the Caucasian nose is on the whole narrow, elongated downwards, and elevated at the bridge; the Mongolian is flat and very broad at its base; the American less flat than the Mongolian, but less prominent than the Caucasian; the Ethiopian flat, broad, and very thick at its base; the Malay full and broad, and, in general, thicker at its apex than the other varieties are. As for the varieties of form in the individuals of the same race or nation, they have little, if any, physiological interest: they are not known to have any connection with differences of function, and the importance they have acquired is founded on the unsupported notion that they are characteristic of corresponding varieties of temper and of intellect.

MORBID ANATOMY OF THE NOSE.

Congenital defects.—The extreme of these is found when the normal state of the very early fœtus continues and the nose is nearly absent. Such a case is described by Soemmering. The child was born at the full term: the brain was malformed, and there were no olfactory nerves. In place of nasal bones there was but one small lens-shaped bone, and the ethmoid bone was little developed: the eyes were close together, but the orbits had not coalesced. A similar example is mentioned by Roederer, in which a child with malformed ears had in place of nose a scarcely perceptible elevation, no nostrils, and for nasal fossæ a blind pouch formed by mucous membrane. Vrolik,† by whom these cases are quoted, describes another in a pig

* Institutiones Physiologicæ.
† Handboek der Ziektekundige Ontleedkunde, D. ii. p. 70.

which is in Sandifort's museum, and in which the olfactory nerves and the nasal, lachrymal, and ethmoid bones are all absent.

Next to these are cases in which the nose exists, but has not its naturally complex form. Otto* describes two such in mature female anencephalous children. The nose was in both flat and broad; it had but one nostril, and the septum was absent. The inferior turbinated bones were approximated posteriorly, so as in one case to close the nasal cavity, and in the other to reduce it to a very narrow aperture opening into the pharynx. In one of these children, also, the olfactory nerves were absent. Sometimes a state like this exists on one side only. Vrolik † mentions a child still living in which the right half of the nose was fully developed, but on the left side there was a kind of snout hanging from the root of the half nose, perforated and giving passage to mucus and air. Professor Broers cut off this appendage and the aperture closed.

The floor of the nasal fossæ remaining in the state which it naturally presents up to the third month, constitutes cleft palate, a slight degree of which, since it produces no inconvenience, is more common than is generally supposed. When the membrane described as closing the nostrils after about the ninth week is not removed, the *atresia narium* results. Several cases fairly referable to this arrest of developement have been recorded.‡

Defects of developement at a later period are seen in the cases of absence of one or more sinuses, of which also several cases have been recorded. And with these, as errors of developement produced perhaps by some accidental pressure, may be enumerated the examples of extreme obliquity or curvature of the septum, in which the apex of the nose is turned completely to one side or even backwards towards the cheek. Such are the cases for the remedy of which Dieffenbach has lately applied with success the subcutaneous division of the cartilages and the adjacent contracted tissues.§ Another slight defect is that in which part of the septum is deficient, or in which the bone is perforated but is closed by membrane. Haller|| describes a case in which the vomer was completely and widely perforated; but much more commonly the defect is in the vertical plate of the ethmoid bone. Very rarely there is an aperture in the cartilaginous part of the septum. The excellent anatomist Hildebrandt had a defect of this kind.¶

A class of cases, which, though congenital, cannot be certainly referred to arrest of developement, are those of *fissure of the nose*. Sometimes the nose alone is said to be divided deeply in the median plane,** and this may represent the fœtal state in which the frontal processes have not united, or in which the septum is not yet formed. But the cases are more numerous in which the fissure exists on one or both sides of the face. In some it extends from the angle of the mouth, through one or both alæ of the nose, to the internal or external angle of the eye, laying into one the cavities of the mouth, nose, and one or both orbits. Four such cases, differing but little from each other, are recorded by Vrolik. He possesses also an example in which, in a much less degree of the same defect, there is only a fissure of the skin from the mouth to the eye by the side of the right ala nasi; and another, in which a deeper fissure extends in the same direction on both sides. These cases, however, like those of hare-lip, cannot be regarded as mere arrests of developement: there is no period in which the fœtus is known to present these as normal conditions.

A very remarkable congenital defect in which the nose is concerned, is that of which the subjects have been called Cyclopian or Cyclocephalian monsters. It has been admirably illustrated in a special memoir by Dr. Vrolik,* who points out five varieties of it. In the first, the eyes are absent or not externally visible, and the nose is either absent altogether or replaced by a kind of proboscis or snout-shaped member, consisting of little more than skin, and attached above the orbit. In the second there is a single orbit in the middle of the forehead which contains a single eye-ball, and above which there is sometimes a proboscis representing the nose. In the third, the eye appears externally to be single, but is internally double; and with this again the nose may exist in the form of a proboscis. In the fourth, the two eye-balls are separated, but they lie in one orbit in contact, or with only a narrow partition between them, and above them there is a proboscis which, as in the other cases, may be curved either upwards or downwards. In the fifth, the proboscis, approaching more nearly to the form of a natural nose, has an osseous nucleus, and is directed downwards; and the eye, above which it is placed, is either double or single. In this series, therefore, there is a regular gradation from the natural to the most unnatural condition, in regard to both the nose and the eyes. For the eyes, there is in some no eye at all; in some a single eye-ball placed in the middle line; in some again an eye-ball, which appears single, contains parts of two; and in some two eye-balls lie close together in a single median orbit. For the nose, it is in some altogether absent; in some it exists in the form of a snout which is little more than a prolongation of skin; in others it has a more or less well-formed osseous nucleus; in some it is curled upwards and backwards, in others directed obliquely downwards: and among all these there are numerous gradations of deformity. Now, any of these conditions of the nose may co-exist with any of those of the eye: there is no regular

correspondence between their respective degrees of developement. This is confirmed by the cases of the monsters in which the eyes are completely absent, but the orbits are naturally placed and the nose is well formed; and by those others already mentioned, in which the nose is absent, but the eyes and orbits are natural and almost naturally placed. From all these, and from the constancy of the deformity of the nose when the orbits are united, it may be deduced that the eye and the nose are developed independently, except in regard to their position, and that the displacement of the nose, which constitutes one of the chief features of the Cyclopian monsters, is generally the consequence of the orbits having taken up the place of the nasal cavities. It cannot be said that the displacement of the orbits is the only cause of that of the nose, because there are a few cases in which the nose occupied the Cyclops position, though the orbits had their natural place; and one case in which the orbits and eyes were absent, and yet the nose was elongated like a proboscis and set high upon the forehead. But these do not invalidate the truth of the general deduction already drawn.

The displacement of the nose is thus explained with much probability by the precedent displacement of the orbits, and the latter is probably due to an arrest in the developement of the eyes. But the cause of the peculiar deformity of the nose is very obscure. There is generally some degree of relation between the approach to completeness of the nose and that of the brain and its nerves, and especially of the anterior lobes and the olfactory nerves: yet these nerves are sometimes present when the nose is most deformed, and when it has neither ethmoid bone nor cavity, nor even any osseous nucleus; and in other cases they are absent when there is a distinct though misshapen external nose. Tiedemann's supposition, therefore, that these, like other malformations of organs, depend on a precedent defect in the corresponding nerves or parts of the nervous centres, cannot be maintained.

Diseases of the nose.—These are so far generally similar to those of the similar tissues in other parts that some of their peculiarities only need be mentioned here.

The *skin* of the nose is perhaps more than any other part of the face subject to the eruptions of acne, &c. And these acquire a somewhat peculiar character from the small vessels of the nose being so liable to distension. In the common *red nose*, all the small veins are usually dilated and in a measure varicose; and even in healthy persons the circulation through the skin of the nose is carried on with comparatively little force, if we may judge by the frequency with which it is partially arrested by cold. This dilatation of the vessels and consequent slowness of circulation not only render the diseases of the nose peculiarly obstinate, but permit them to produce changes of structure which are very rarely found among their defects in other parts. Such is the tuberculated induration and thickening with deep red or livid congestion of the skin after long-continued acne, in which all the deeper textures appear to be confused in one hard brawny substance. When this state continues very long and the congestion somewhat abates, the thickened tissues remain, and sometimes grow into a kind of pendulous tumour from the end of the nose. Such tumours, (which, however, may form with little precedent acne,) are usually three-lobed, one portion seeming to correspond to the end, and one to the fore part of each of the alæ, of the nose. One which I dissected was composed throughout of a compact, white, fibro-cellular tissue, like that of which the pendulous tumours consist which grow from other parts of the skin, and especially from the female labia. It seemed very little vascular,* and the hair-follicles and sebaceous glands were enormously enlarged. Some of the latter measured not less than a line in width, and their ducts, which opened at the bottoms of deep fossæ, admitted full-sized bristles. The same enlargement of these organs takes place in certain large growths of the skin of the scrotum.

The position of the *cavities of the nose* has been an effectual hindrance to the examination of the changes of structure produced by their ordinary diseases. Nothing is known of the state brought on by repeated *colds*. While they continue, the mucous membrane is gorged with blood, swollen, and red, so as to close, with the assistance of the increased secretion of mucus, the passage to the pharynx. Probably the mucous membrane is in time condensed and thickened; and from this it may result that in looking over a number of sections of heads, the Schneiderian membrane is found by no means uniform in its thickness, consistence, or vascularity even on corresponding parts.

M. Mareschal† has lately stated that, in the examination of eight persons who had had epistaxis shortly before their deaths, he found in all a circumscribed portion of the membrane which was very congested, and dark red or livid. In two of them this congested part was situated anteriorly, near the junction of the septum and the floor of the nostrils; in the others posteriorly on the fold of mucous membrane at the lower border of the inferior turbinated bone.

Simple abscesses sometimes occur beneath the mucous membrane of the nose, especially after injuries; and after passing through an ordinary course leave their usual effects in thickening, induration, and unnatural adhesion of the cicatrized tissues.

A *thickening of the mucous membrane* simulating polypus has been already mentioned. It occurs especially in scrofulous children and young persons, and presents the same characters, as to its duration and progress, which are observed in the other chronic inflammations to which they are subject, and with one or more of which it is commonly associated. This spongy thickening

* Sir W. Blizard lost a patient through hemorrhage after the removal of a tumour of this kind from the nose; but it is possible that this might have been owing to something wrong in the general state of the patient, for usually little blood is lost in such operations.

† Annales de Chirurgie, Janvier, 1843.

usually affects at once the whole or a large portion of the membrane, though, of course, it is most obvious at the folds on the borders of the turbinated bones. It is sometimes attended by superficial ulceration or excoriation of the membrane; but even without either of these the discharge has usually a purulent character. If it continue long, this chronic inflammation produces not a mere swelling, but a more solid thickening and induration of the membrane sufficient nearly to close the passage through the nose; or if there have been ulceration of the membrane, a part of the passage may be closed by adhesion of the opposite surfaces of the thickened and approximated membranes. Such obstructions are usually situated near the entrance of the nasal ducts, and when the swelling of the membrane which preceded their formation has decreased, they are drawn out, and look like transverse thin membranes passing across the cavity, just within the nostrils. Such obstructions are particularly apt to occur when, by obliquity of the septum, one of the nasal cavities is unnaturally narrow.

Sometimes, from chronic inflammation of the mucous membrane of the nose, substances are produced altogether unlike the discharges commonly seen. Mr. Cæsar Hawkins, who has paid much attention to these diseases, speaks of "several portions of substance like chalk in consistence, exceedingly fœtid, and in shape exactly like the spongy bones: they were probably composed of phosphate, or perhaps carbonate, of lime, with fetid mucus secreted from the upper spongy bones." A similar case, probably, in which a hard concretion was found in a nose, is recorded by Dr. Grandoni.* In another case, Mr. Hawkins saw small bodies, like half-formed cartilage, which had the shape of the superior spongy bone, and which had been occasionally separated during many years; and in another, a very tough and tenacious mucus which was constantly secreted from a soft and relaxed membrane covering a diseased vomer. The exact condition of the membrane in these cases has not been determined; in one it seemed connected with diseased bone. The secretion of earthy matter from it is perhaps analogous to that which produces the phosphatic incrustations of the diseased mucous membrane of the urinary bladder.

The ulceration of the mucous membrane of the nose which attends this state of chronic inflammation is usually superficial. Deep and destructive ulcerations (such as give rise to the symptoms of *Ozæna*) occur, however, under many circumstances; for example, from neglected injuries, scrofula, syphilis, &c. Their effects are often not confined to the membrane, but are propagated either to the skin, through all the intermediate tissues, or to the subjacent cartilage or bone, which then are ulcerated or suffer necrosis secondarily, as, more rarely, they do primarily. The appearances of the ulcers from various causes do not materially differ. They may commence in any part of the nasal cavities; but they are said to be most frequent near the exterior in common or scrofulous ulceration, and in the more interior parts of the membrane in syphilis. Their first appearance is in the form of a small pustule or collection of matter beneath the membrane; and the ulceration by which this opens externally makes progress more or less rapidly, spreading in both extent and depth without any signs of resistance to its course in the adjacent textures. When such ulcers have exposed the cartilages, these are gradually perforated by the ulcerative process; they do not suffer necrosis, but in this, and probably in all their morbid changes, they follow the course of the articular cartilages, which they resemble in their structure and in their exemption from being ossified. The septum is the part in which the effects of such ulcers are most commonly seen. Sometimes it is perforated through its centre, and, in these cases, though the aperture be large, the shape of the nose may be unaltered, for the remaining borders are sufficient for its support. But when a part of these borders is destroyed, deformity is the certain result; the point of the nose is drawn backwards and downwards when the lower part of the septum is destroyed; or the middle of the bridge falls in, and the point projects and is turned upwards when the upper part is lost; or, when the destruction is more general, the nose falls nearly flat below the nasal bones. When the ulceration reaches the bones it may continue to spread through them, destroying them gradually without necrosis; or, if its progress be rapid, or matter collect beneath the periosteum, so as to expose a large surface of bone, this being deprived of its supply of blood, perishes and gradually exfoliates. Thus, the nasal bones, or large portions of the septum, or the turbinated bones, and parts of the palate may be destroyed, and the most hideous deformities be produced. Sometimes, no doubt, the syphilitic affections of the nose may commence in the bones or cartilages themselves; but, most commonly, they are affected secondarily after being exposed by the destruction of the mucous membrane. In the worst cases, the ulceration spreads with a ragged sloughing to the membranes of the palate, pharynx, and other adjacent parts, and through them to the bones and other tissues which they cover. The disease has its centre of severity in the nose, but the pain around the nasal cavities indicates a simultaneous slighter affection of the adjacent sinuses; sometimes, also, it extends to the membranes and substance of the brain; and sometimes it passes up the nasal duct and produces all the signs of fistula lacrhymalis.

Polypi.—The mucous membrane of the nose is more subject than any other part to the growth of polypi, which may occur in either one or both of the nasal fossæ, or in the cavities adjacent to the nose. Those which grow in the fossæ, and which alone will be considered here, are of several kinds, and, though the lines of distinction cannot be clearly drawn between them, are commonly arranged as vesicular, gelatinous, fibrous, and malignant polypi.

* Annali Universali di Medicina, Ottobre, 1840.

The *vesicular polypi*, or, as they have been called, *hydatid polypi*, are composed of masses of large, pellucid vesicles, filled by a transparent and slightly viscid fluid, or consist of a substance somewhat like the vitreous humour. They can be broken by a very slight force, and after they have discharged their fluid nothing remains but shreds of fine membrane, like films of washed fibrine. They commonly grow from the upper and side walls of the nasal fossæ, and their growth is very rapid. They frequently also burst spontaneously, discharge their contents, and are reproduced; and their reproduction is almost always very rapid when they are artificially destroyed, and the patient is not in other respects effectually treated. The thin membrane investing them is easily permeable, and their size varies according to the rapidity with which evaporation can take place from them, so that they may serve as a sort of hygrometer, indicating by their size the relative quantity of moisture in the atmosphere. Their nature is as yet unknown; they are probably entirely new productions, and not, as some think, distended mucous follicles.

Gelatinous polypi are more common than those of any other kind, and are those which are commonly called *mucous polypi*, though, under this term, Boyer and some others include both these and the preceding variety. They are much firmer than the vesicular polypi, and grow in one or more distinct and circumscribed masses. They are of a dull white or yellowish colour, soft and easily torn, composed of a fine tissue with fluid infiltrated in it, like anasarcous cellular membrane. Generally they appear to have a few opaque white filaments running through their substance, and their surface and interior are traversed by long meandering bloodvessels. When small, they are nearly round and elongated; but as they increase they adapt themselves, as the other kinds also do, to the form of the nasal cavities, spreading towards their apertures, but rarely having sufficient force of growth to expand the firmer parts of the nose. They almost always grow nearer the anterior than the posterior nares, from about the middle of the outer wall of the nose, or from the middle turbinated bone, to which they are fixed by a narrow base more or less deeply rooted in the tissue of the Schneiderian membrane, and sometimes tightly adherent to the bone. It is only very rarely that this or either of the other innocent forms of polypus grows from the septum; but Mr. Hawkins has seen one example. Sometimes one only grows at a time, but more often there are several crammed together. They are covered by a fine membrane, like a thin continuation of the mucous membrane of the nose, like which, also, it is said to be covered by ciliary epithelium and appears to produce mucus. A polypus of this kind, which I recently examined, was composed throughout of a tough interlacement of fine, crooked, pale filaments like those composing a fibrinous coat of blood, in which there were thickly embedded a vast number of flat, circular, granulated cells, or cells with granulated nuclei. Each cell was about $\frac{1}{2000}$th of an inch in diameter, and in each, three or four of the granules appeared much darker than the rest. The whole presented on dissection a tough fibrous *grain*, and appeared to the naked eye much more highly organized than the microscope proved it to be. From its minute structure, which resembled in its general characters that of many other kinds of tumours, it is evident that these polypi, as well as the last, are not mere changes or out-growths of the mucous membrane, but are altogether new productions and belong to the class of tumours rather than to that of degenerated tissues.

Fibrous, sarcomatous, or *fleshy polypi* are masses of firm, well organized, and vascular tissue, growing like the others from a comparatively small base. Their substance is of a pale reddish or brownish colour, and they are invested by a thin smooth membrane. In different examples their degrees of firmness differ, so that, on the one hand, it is not easy to draw a line between this and the preceding variety, and, on the other, some specimens of this are found nearly as hard as the denser fibrous tissues. The base, or pedicle, of these growths is usually firmer and more fibrous than the rest of their substance, and parts of them are composed sometimes of tissues like cartilage or bone. Like the preceding they grow from the outer wall of the fossæ, but from the posterior, more often than from the anterior, part. Sometimes one only is produced, sometimes several; and their force and rapidity of growth are sufficient to stretch, if unchecked, all the parts around them, to expand and destroy the bones, and protrude through the skin of the face, where ulcerating they may present nearly all the characters of malignant diseases. And this resemblance to malignant growths becomes the greater from the polypus itself softening and growing more vascular on its surface or even throughout its substance.

The apparent transition from the preceding to this variety of polypus makes it probable that these also are new formations; and though they are sometimes firm and apparently fibrous even when they are very small, yet perhaps they are often produced by the further developement of the gelatinous variety. Mr. Hawkins says that, in general, when the polypus grows from the surface only of the mucous membrane it is soft and gelatinous; but if the whole thickness of the membrane, including also the periosteum, be its seat, or if it grow from a part where there is much fibrous tissue, as for example, near the posterior nares, it is fibrous; and this, no doubt, is generally true; yet the frequency with which portions of the turbinated bones are pulled away in extracting gelatinous polypi proves that these also have often deep attachments.

What are called *malignant polypi* of the nose do not truly deserve the generic name. They are cancerous diseases of the mucous membrane or of the parts situated on its exterior, from which they gradually make their way into the nasal cavities. In general characters they do not differ from the similar diseases of other parts. One form in which they appear is, that of common cancer of the mucous membrane analogous to the hard or warty cancer of the skin, and pursuing the same course of apparently unresisted ulceration as that disease does. It occurs in old persons, and usually makes its progress very slowly, destroying all the adjacent parts till the patient is exhausted, or till it affects by its contiguity the brain, as in a case mentioned by Mr. Hawkins. The other chief form in which the nose is affected by malignant disease is that of the soft or medullary cancer; but it is not certain whether this has yet been seen as a primary disease of the mucous membrane, or whether it be not always seated at first in some deeper tissue, from which as it makes its way it acquires a covering from the mucous membrane, and appears to be truly a disease of the nose. Whichever it be, there is nothing peculiar in its characters or course to need a special description of it here.

(James Paget.)

NUTRITION.—The function thus designated may be regarded as including, in the most extended acceptation of the term, the whole series of operations, by which the alimentary materials are converted into living organised tissue: but as many of these changes are separately treated of in other parts of this work, we shall here confine ourselves to a more limited range; and shall consider the nutritive process as commencing with the absorption of the materials, which have been prepared by the digestive process; and as including all the changes, which are involved in the conversion of the fluids so introduced within the system, into solid organised tissue, forming an integral part of the fabric.

The *object* of the process of nutrition is the continual production of new tissue, either for the augmentation of the original structure, or for the reparation of that part of it, which is continually undergoing decay or disintegration. And by this continual renewal of the tissues, we gain, as will hereafter appear, a constant reinvigoration of those vital powers or forces, the exercise of which has been one of the chief causes of the previous *waste*. It is a principle now generally acknowledged by physiologists, that the processes of disintegration and decay, in any organ or tissue, are more rapid, in proportion to the functional activity which it has been called on to manifest;* and we find that the tendency to decomposition in the different tissues after death, which doubtless bears a general relation to their respective needs of renewal during life, is the greatest in those, whose *vital* powers are most remarkable—the nervous and muscular tissues for instance; whilst it is the least in those, whose properties are most purely *physical*—such as bone, cartilage, yellow elastic tissue, &c. Hence it is in the former that the greatest activity of nutri-

* This doctrine, strongly put forth in regard to the muscular system by Liebig, and restricted to it by him, had been taught long before the publication of his treatise.

tion is required, for the maintenance of their normal texture and properties; but its amount will vary, according to the demand created by previous activity, and the consequent decay.

The materials required for the nutrition of the tissues of the animal body seem to be supplied, for the most part at least, in forms possessing a similar chemical composition, by the vegetable kingdom. It will be presently shown that albumen may be regarded as the *pabulum*, at the expense of which all the organised textures (properly so called) of the animal fabric may be constructed. The really-organised part of this fabric, indeed, appears seldom to depart widely from the *protein* type of composition. Thus in fat, the non-azotized matter is contained within cells, whose walls are composed of a protein principle; and in the nervous tissue, it is probable that the walls of the cells and tubes are composed of an albuminous compound, though their interior is occupied by a substance of a character much more nearly approaching that of fat. Even with respect to the *gelatinous* tissues, as they are termed, there is much doubt to what extent they contain gelatin in their normal state; for where this can only be extracted from them by long boiling, it is not improbable that an actual conversion takes place; since we know that pure fibrin may be converted, by long boiling, (which occasions the liberation of ammonia,) into a compound resembling gelatin in many respects. And in those which are most purely gelatinous, it is doubtful how far the gelatin is itself organized. The writer has lately examined the *sound* of a cod with great care, both before and after the action of hot water upon it, and is satisfied that the gelatinous portion of it exhibits nothing that can be properly called organization—the only distinct appearances of fibres, cells, &c., being presented by portions which were left undissolved by the hot water, and which were, therefore, to be regarded as more allied to albumen than to gelatin in their composition. Similar remarks may be made in regard to the horny substance deposited in certain tissues; and it may probably be stated as a general theorem, that whilst in the plant, the materials which it derives from the elements around are combined and elaborated into non-azotized compounds for the production of organized tissue, and into azotized products for deposition in its cavities, these last alone form the materials of the animal organism, any non-azotized substances contained in it being inorganic in their condition.

In considering the various stages of the nutritive process in animals, we shall do well to bear constantly in mind the leading facts in regard to the same process in the simplest cellular plant: for we shall find that the elementary parts of the most complex animal organism go through a series of changes essentially the same; so that the *type* of the function is everywhere uniform, notwithstanding the vast apparent differences in the mode in which it is performed. The cell of the red snow or yeast plant, for instance, is developed from an almost imperceptible germ, by its own power of attracting to itself certain nutritive materials in its neighbourhood, which it combines into the new forms required both for its own growth and increase, for the elaboration of certain peculiar matters contained in its cavity, and for the production of the germs of new cells; and these, being liberated in time by the death of their parent, go through, in their turn, the same series of changes. We shall now trace these changes in the highest and most complex form in which they are presented to us;—that is, as they occur in man, or any vertebrated animal.

Elaboration of organizable materials.—The alimentary substances taken in by the absorbent vessels require to undergo very important changes within the body, before they can be applied to the nutrition of its structure. The chief constituents of the chyle, as at first absorbed, are *albumen* and *fat;* the former is destined to be converted into the material of the solid tissues; the latter is chiefly designed for the maintenance of the animal temperature, by the combination it is made to undergo with the oxygen introduced through the lungs. It is questionable, as already explained, whether fatty matter, or any other non-azotized compound, can ever be applied to the *nutrition* of the animal body. Even if it should be ever proved to be subservient to the re-construction of the azotized tissues, there can be no doubt that it must have been first converted into an *albuminous* compound—that is, into some modification of protein; and as the evidence that such a transformation ever takes place is far from being satisfactory, we have as yet no data for examining the mode in which it is effected. We shall, therefore, consider *albumen* as the starting-point of the animal tissues, and shall endeavour to trace, so far as the present state of our knowledge admits, the processes by which this is converted into the organized fabric.

In this assumption we seem justified by two very obvious considerations. First, in the egg of a bird, (or any other oviparous animal,) we find that, putting aside the fatty matter of the yolk, albumen is the sole organic compound, at the expense of which *all* its tissues are to be formed; so that, by the wonderful processes of chemical and vital transformation, which take place during the period of incubation, the albumen which it contained at first is metamorphosed into bone, cartilage, nerve, muscle, tendon, ligament, membrane, areolar tissue, gelatinous matter, horny substance, feathers, &c., &c. Secondly, a similar metamorphosis appears to be continually taking place in the body of the adult animal; for every *protein compound* employed as food appears to be reduced to the form of albumen in the digestive process; so that this becomes the *essential* constituent of whatever fluid is absorbed for the nutrition of the tissues. It is true that gelatin, taken in as food, may be absorbed and carried into the current of the circulation; but there is no doubt that it is altogether incapable of being applied to the re-construction of any but the gelatinous tissues; and, as already stated, it seems questionable whether, even in these, it exists in a condition that can rightly be termed organised. Moreover, as it is clear that the gelatinous tissues *may* be formed at the expense of albumen, we are justified in regarding this substance as the common *pabulum* for all.

In order to form a definite conception of the nature of the transformations, which this principle is destined subsequently to undergo, it is important to bear in mind, *in limine*, that albumen cannot be regarded as possessed of any properties that characterize it as a *vital* compound—or, in other words, that essentially distinguish it from compounds of an ordinary *chemical* nature. In its coagulability by heat or by acids—in its combination with alkalies as an acid, or with acids as a base—and in the absence of any power of spontaneously passing into forms more decidedly organic than the granules which are seen when it is made to coagulate slowly—it is closely analogous to many substances which belong to the domain of inorganic chemistry. It appears, then, to be totally unpossessed of the property of *plasticity;* by which we mean the power of being at once converted into organised tissue: so that any deposit, whether fluid or solid, which mainly consists of albuminous matter, must be regarded as *aplastic*. This is a principle of great importance, as we shall see further on.

Before albumen is ready to be appropriated by the tissues as the material for their nutrition, it must undergo a very important change—not so much, however, in its chemical composition, as in the re-arrangement of its particles in a new mode, by which its properties are essentially changed. There seems reason to believe that, in the proportions of its ultimate elements, it is identical with the substance termed *fibrin*, into which it is changed during its passage through the chyliferous and sanguiferous vessels. [See ALBUMEN and FIBRIN.] But there are such decided and well-marked differences between these two compounds, as indicate that they fulfil entirely different purposes in the animal economy; and that whilst, chemically speaking, they are *isomeric*, the fibrin is endowed with properties of a distinctly *vital* character—that is, altogether different from any with which mere chemistry brings us acquainted. One of the most obvious manifestations of this difference is the property which is universally regarded as distinctive of fibrin—its tendency to coagulate spontaneously when withdrawn from the living vessels, and to pass into the form of a *tissue* more or less definitely organised. As will presently be shown, the completeness of this transformation depends upon two circumstances in particular;—the perfect elaboration of the fibrin itself, and the vitality of the surface upon which the concretion takes place. When the fibrin is highly elaborated, it will coagulate in the form of a definite network of minute fibrillæ, even upon a dead surface, as a slip of glass; this is the case, for instance, with the fibrin of the buffy coat of the blood, or with that of the liquor sanguinis (coagulated lymph,) poured out for the reparation of an injured part. But in the ordinary fibrin of the blood, the fibrillation is less distinct, when the concretion takes place upon a dead surface. When it occurs in contact with a living surface, however, the coagulation takes place more gradually; and it seems as if the particles, having more time to arrange themselves, become aggregated into more definite forms, so that a more regular *tissue* is produced—just as crystals are most perfectly formed, when the crystalline action takes place slowly. It was formerly imagined, that the muscular tissue is the only one produced at the expense of the *fibrin* of the blood; the other tissues being formed from its *albumen.* This, however, is unquestionably erroneous. There is no proof whatever, that albumen, as long as it remains in that condition, ever becomes organised; whilst, on the other hand, there is abundant evidence that the *plasticity* of any fluid deposit—that is, its capability of being metamorphosed into organised tissue—is in direct relation with the quantity of fibrin which it contains. Thus the liquor sanguinis or coagulated lymph, thrown out for the reparation of injuries, contains a large amount of fibrin; and this substance is converted, not at first into muscular fibre, but (whatever may be the tissue to be ultimately produced in its place) into a fibrous network, which fills up the breach, and holds together the surrounding structure. This may be regarded as a simple form of *areolar* tissue, which gradually becomes more perfectly organised by the extension of vessels and nerves into its substance, and in which other forms of tissue may subsequently make their appearance. This process will be more particularly described hereafter; it is at present noticed here, as an illustration of the general fact, that *fibrin* is to be regarded as the *plastic* element of the nutritive fluids.

The change from albumen to fibrin is, therefore, the first important step in the process of assimilation. It commences in the absorbent system; for the chyle is usually found to contain fibrin, even *before* it enters the mesenteric glands (as is indicated by its tendency, however feeble, to spontaneous coagulation); and *after* it has passed through them, the quantity of fibrin is considerably increased, so that chyle drawn from the thoracic duct usually coagulates with tolerable firmness. This process of elaboration continues in the blood: for the quantity of fibrin it contains is always kept up, in health, to a certain standard, although there must be a continual withdrawal of it for the nutritive processes, without a corresponding regular supply from the chyle; and we find it, moreover, undergoing a sudden and remarkable increase, under the influence of local agencies. The question naturally suggests itself, therefore—what is the cause of this change? It has been usually attributed to some influence effected upon the albuminous fluid, by the living surfaces over which it is passing; and the increase in the amount of fibrin in the chyle, which is specially noticed after its passage through the mesenteric glands, has been thought due to some peculiar action of the blood that may come into relation with it, through the thin walls of that capillary plexus, which forms, with the convoluted lacteal tubuli, nearly the whole bulk of those bodies. The writer is inclined to attribute it, however, to another agency—the vitalizing influence of certain floating cells, which the chyle and the blood contain; and the chief points of the evidence of this doctrine will now be set forth.

A comprehensive survey of the vital processes, performed both by plants and animals, enables us to bring together a number of examples in which *cells* are developed in a temporary manner, growing, arriving at maturity, and then disappearing; apparently without having performed any particular function. In the albumen of the seed, for instance, this often takes place to a remarkable extent. In the yolk of the egg there is a similar transitory developement of cells, of which several generations succeed each other, without any permanent structure being the result. In the germinal vesicle, again (according to Dr. Barry*), several annuli of cells are seen to occupy its cavity, when it is prepared for fecundation; and the oldest and largest of these contain another generation: yet all these disappear by liquefaction, as soon as the two *permanent* cells begin to be developed in the centre. Further, in the subsequent developement of all the cells which are descended from these, and form the "mulberry mass," the same process is repeated; a great number of temporary cells being produced, only to liquefy again as soon as the two permanent central cells make their appearance. It can scarcely be imagined by the well-judging physiologist, that all this *cell-life* comes into existence without some decided purpose; and if we can assign to it an object, the fulfilment of which is consistent with the facts supplied by analogy elsewhere, this may be reasonably considered as having a fair claim to be received as a physiological induction.

In all these instances, and in many more which might be quoted, the crude alimentary materials are being prepared to undergo conversion into permanent and regularly organised structures. The very first union of the inorganic elements into the simplest proximate principles is effected by the *cell-life* of plants. The change of these principles into the peculiar compounds which form the characteristic secretions of plants, is another result of their cell-life. And there seems equal ground for the belief, that the change of the proximate principles, sugar and gum (of which the latter appears to hold the same place in the vegetable economy that albumen does in the animal), into the peculiar glutinous sap, which is found wherever a formation of new tissue is taking place, is equally dependent upon the agency of cells. The process is probably commenced in the leaves; but as the ordinary descending sap, which is the product of their elaboration, is not so remarkable for its *plasticity* as the fluid drawn from certain rapidly growing parts, it seems probable that a local agency takes place in these, analogous to that which we shall be able to trace in certain conditions of the animal economy. Thus, the starchy fluid which is contained in the ovule, previously to its fecundation, is probably not in the state in which it can be immediately rendered subservient to the nutrition of the embryo; and the developement of successive generations of cells, which exert upon it their vitalizing influence, may be reasonably regarded as the means by which the requisite change is effected. Exactly the same may be said of the albuminous matter contained in the yolk of the egg, which is certainly not in a condition in which it can be immediately applied to the purposes of nutrition; and its conversion may be regarded as commencing with the developement of transitory cells within its own substance, and as being completed by means of the cells forming the inner layer of the germinal membrane, by which it is subsequently taken up and introduced into the current of blood flowing through the vascular area. A similar purpose is probably answered by the transitory cells developed within the germinal vesicle; and by those which appear at a similar period in the evolution of the descendents of the "twin cells" produced in it.

Many other examples of a similar process might be adduced, but they would all lead to the same general conclusion, which harmonizes well with the important principle of general physiology,—that the higher the grade of structure ultimately to be attained by any part, and the more permanent its character is destined to be, the longer and more elaborate are the preliminary stages of its evolution. As an instance of this law, which bears a remarkable *analogy* with the facts just recorded, we may advert to the production of a *temporary* respiratory apparatus in the higher plants and animals, corresponding with that which is permanent in the lower parts of the scale. There are probably cases, however, in which cells are very rapidly called into existence, without that preparatory elaboration of their nutrient materials, which we regard as due to the vital operations of a preceding generation. Thus the *Bovista giganteum*, a large fungus of the Puff-ball tribe, has been known to increase, *in a single night*, from a mere point to the size of a huge gourd, estimated to contain 47,000,000,000 cellules. In such a case it is difficult to suppose that any but the most rapid mode of generating cells can have been in operation; and the idea that these could not have been developed by any such elaborate process as that just alluded to, is borne out by the fact of their extremely transitory character, the decay of such a structure being almost as rapid as its production. The same may be remarked of those *fungous* growths in the animal body which sprout forth most rapidly. Hence the apparent exception assists in proving the rule.

We have thus a class of facts which indicates that the conversion of the chemical compound into the organizable principle—the *aplastic* into the *plastic* material—is effected in the particular situations where it is most wanted by the vital agency of transitory cell-life; that is, by

* Embryological Researches, third series.

the production of cells which are not themselves destined to form an integral part of any permanent structure, but which, after attaining a certain maturity, reproduce themselves and disappear, successive generations thus following one another until the object is accomplished, after which they altogether vanish. We shall now consider another class of facts which seem to indicate that a change of this kind is being continually effected in the nutritious fluids of animals during their circulation through the body, by cells which are either carried about with them, or which are developed for the purpose in particular situations, as in plants. The former is the more common occurrence; since the conditions of animal life, usually involving a general movement of the body, require also a constant *general* reparation of its parts, and an adaptation of the circulating fluid therefore to the wants of the whole fabric.

In the chyle drawn from the lacteals near the intestinal tube, there is but little fibrin; and very few of the peculiar chyle-corpuscles are seen in the fluid. In the chyle of the mesenteric glands, on the other hand, the corpuscles are extremely numerous; and they are always readily seen in the chyle of the central lacteals, receptaculum chyli, and thoracic duct,—though their number is considerably less than in chyle drawn by pricking the lacteals of the mesenteric glands. The average size of these corpuscles is about $\frac{1}{4600}$th of an inch; but they vary from about $\frac{1}{7000}$th to $\frac{1}{2600}$th. The smallest are usually found in the peripheral lacteals; the largest in the thoracic duct. They are evidently *cells* in process of developement; and from the appearances presented by those which are seen in the chyle of the thoracic duct, there can be little doubt that they have the power of reproducing themselves in the ordinary mode. The first appearance of these cells in large number is exactly coincident with the first appearance of fibrin in the chyle,—at least to an amount sufficient to produce spontaneous coagulation; and the delay of the chyle in the mesenteric glands appears to aid in their developement, and to assist their operation. In the lower Vertebrata the absorbent system has none of these (so called) glands; and hence we see that they are not *essential* to the performance of its functions. But in such animals the vessels are immensely extended in length; whilst in the warm-blooded Vertebrata, in whose conformation the principle of concentration operates to the greatest possible extent, we see no such prolongation; the end being answered by the excessive convolution of the absorbents in the mesenteric glands, where it seems probable that the chyle is delayed during the developement of its characteristic cells. Similar statements apply to the *lymph*, and to the lymphatic vessels and glands. This fluid is probably to be regarded, not as a product of the decomposition of the tissues, which is destined to be thrown out of the system, but as the product of that secondary digestion, by which a portion of the materials that have formed a component part of the tissues, and have been set free by their disintegration, is again rendered subservient to nutrition, and reconveyed into the current of the circulation. Into the arguments in favour of this view (which differs from the ordinary doctrine regarding the function of the lymphatic system) we cannot here enter; but it may be remarked that the animal matter of the lymph is mainly of an albuminous character, and that it gradually undergoes a transformation into fibrin during its passage through the absorbent vessels and glands.

The continuation of this process in the blood is believed by the writer to be effected by means of the *white*, or *colourless*, corpuscles, to which increased attention has lately been directed. That these are *identical with*, or are the immediate *offspring of*, the corpuscles of the chyle and lymph, there seems much reason to believe from their similarity in size and appearance. Whilst the *red* corpuscles vary in dimension from less than $\frac{1}{12000}$th of an inch (Musk Deer) to $\frac{1}{337}$th (Proteus), the colourless corpuscles have not been observed to depart widely from the diameter of $\frac{1}{3000}$th of an inch in any vertebrated animal; consequently, while they are but little larger than the average of red corpuscles in man, and are scarcely distinguishable from them, except by the practised microscopist, they are far more minute than the oval blood-discs of reptiles and fishes, and are at once recognised, even by a cursory observer. Now it is a fact of great physiological interest and importance, that whilst the *colourless* corpuscles are to be met with in the nutritious fluids of *all* animals, which possess a distinct circulation, the *red* corpuscles are restricted to the blood of Vertebrata. This observation, which was first put forth by Wagner,* has been confirmed by the writer of this article, who had been previously struck with the very close analogy between the floating cells carried along in the current of the circulation in some of the very transparent aquatic larvæ, (especially those of the Culicidæ,) and the lymph-corpuscles of the Frog. Now it is evident from this fact, that, as the *blood* of Vertebrata is distinguished from their *chyle* solely by the presence of red corpuscles in the former, and by their absence in the latter, the nutritious fluid of invertebrated animals is rather analogous (as Wagner has remarked) to the chyle and lymph, than to the blood of Vertebrata. Or, to put the same idea in another form, the presence of the colourless corpuscles in the nutritious fluids appears to be the most general fact in regard to its character throughout the whole animal scale; whilst the presence of red corpuscles in that fluid is limited to the vertebrated classes. Hence it would not be wrong to infer that the *function* of the colourless corpuscles must be of a *general* character, and intimately connected with the nutritious properties of the circulating fluid; whilst the function of the red corpuscles must be of a *limited* character, being only required in one division of the animal kingdom. Further, it has been noticed by Mr. Gulliver that in the very young embryo of the Mammalia, the white globules are nearly as nume-

* Physiology, by Willis, Part II.

rous as the red particles: this, Mr. Gulliver has frequently noticed in fœtal deer of about an inch and a half long. In a still smaller fœtus the blood was pale from the preponderance of the white corpuscles. It is, therefore, a fact of much interest that, even in the mammiferous embryo, at the period when growth is most rapid, the circulating fluid has a strong analogy to that of the Invertebrata. It then, too, bears in other respects the most striking analogy to chyle; since it consists of the fluid elaborated from the organizable matter supplied by the parent, and *directly* introduced into the current of the circulation. The function of the placental vessels may be regarded as double; for they are at the same time the channel, through which the alimentary materials supplied by the parent are introduced into the circulating system of the fœtus, and the medium of aerating the fluid which has traversed the fœtal system. Hence the placenta may be regarded as at once the *digestive* and the *respiratory* apparatus of the fœtus, and the fluid circulating through the cord as at once chyle and blood. It is not until the pulmonary and lacteal vessels of the embryo have commenced their independent operation, that the distinction between the *blood* and the *chyle* of the fœtus becomes evident; and we should expect, therefore, to find that the circulating fluid, up to the time of birth, contains a large proportion of white corpuscles, which is actually the case. There is a gradual decrease, however, in their proportional number, from the earlier to the later stages of embryonic life, in accordance with the diminishing energy of the formative processes. It has been also observed by Wagner* that the number of colourless corpuscles is always remarkably great in the blood of well-fed frogs just caught in the summer season; and that it is very small in those, which had been kept long without food, and in those examined during the winter.

The most remarkable evidence, however, of the connection between the generation of white corpuscles in the blood, and the production of fibrin, is derived from the phenomena of inflammation. A decided increase in the normal proportion of fibrin in the blood (from $2\frac{1}{2}$ to $3\frac{1}{2}$ parts in 1000) may probably be looked upon as the essential indication of the existence of the inflammatory condition. For it appears from the observations of Andral and Gavarret (which have been confirmed by many other pathologists) that such an increase *uniformly* manifests itself, when a local inflammation commences,—even when the proportion of fibrin has previously been abnormally low, as in febrile diseases; that it bears a constant relation with the extent and intensity of the diseased action; and that it diminishes with the abatement of the morbid condition of the part affected. In some instances, the proportion of fibrin was seen to rise as high as 9 or even 10 parts in 1000; but an increase to the amount of 6, 7, 8 parts, was more common. That this production of fibrin is due to a *local* change can scarcely be doubted; since it is frequently observed to commence before any *constitutional* symptoms manifest themselves; and it may be regarded, in fact, as one cause of these symptoms. Now the recent microscopic observations of Mr. Addison* and Dr. Williams,† which were made independently of each other, have established the important fact, that a great accumulation of white corpuscles takes place in the vessels of an inflamed part; and this seems to be caused at first by a determination of those already existing in the circulating fluid, towards the affected spot; but partly by an actual increase or generation of these bodies, which appear to have the power of very rapidly multiplying themselves. The accumulation of white corpuscles may be easily seen, by applying irritants to the web of a frog's foot. Mr. Addison has noticed it, in the human subject, in blood drawn by the prick of a needle, from an inflamed pimple, the base of a boil, the skin in scarlatina, &c. And the writer, without any knowledge of these observations, had remarked a very obvious difference between the proportions of white corpuscles, in blood drawn from a wound in the skin of a frog immediately upon the incision being made, and in that drawn a few minutes after; and had been led, like the observers just quoted, to refer this difference to a determination of white corpuscles to a part irritated. The absolute increase, sometimes to a very considerable amount, in the quantity of white corpuscles in the blood of an inflamed subject, has been verified by Mr. Gulliver and several other observers. These facts, therefore, afford strong ground for the belief, that the production of fibrin in the blood is closely connected with the development of the white corpuscles; and when we consider them in connection with the facts previously urged, there scarcely appears to be a reasonable doubt, that the elaboration of fibrin is a consequence of this form of cell-life, and is, in fact, its express object.

A recent observation of Mr. Addison's, moreover, would seem to indicate, that no inconsiderable proportion of the fibrin of the circulating blood is contained within the white corpuscles. "Provide six or eight slips of glass, such as are usually employed for mounting microscopical objects; and as many smaller pieces. Having drawn blood from a person with rheumatic fever, or any other inflammatory disease, place a drop of the colourless liquor sanguinis, before it fibrillates, on each of the large slips of glass; cover one *immediately* with one of the smaller slips, and the others one after another *at intervals of thirty or forty seconds*: then, on examining them by the microscope, *the first* will exhibit colourless blood corpuscles in various conditions, and numerous white molecules distributed through a more or less copious fibrous network; and *the last* will be a tough, coherent, and very elastic membrane, which cannot be broken to pieces nor resolved into

* Op. cit. p. 245.

* Medical Gazette, Dec. 1840; Jan. and March, 1841.

† Medical Gazette, July, 1841; and Principles of Medicine, pp. 209, 210.

smaller fragments, however roughly or strongly the two pieces of glass be made to rub against each other. This is a 'glaring instance' of a compact, tough, elastic, colourless, and fibrous tissue, forming from the colourless elements of the blood; and the several stages of its formation may be actually seen and determined. Numerous corpuscles may be observed, in all these preparations, to have resolved themselves, or to have fallen down into a number of minute molecules, which are spread out over a somewhat larger area than that occupied by the entire corpuscles; and although still retaining a more or less perfectly circular outline, yet refracting the light at their edges, in a manner very different from that in which the corpuscles themselves are seen to do. It is from these and various other larger and more irregular masses of molecules on disintegrated corpuscles, that the fibrinous filaments shoot out on all sides, as from so many centres; or frequently the filaments are more copious in two opposite directions."*

A different view of the cause of the production of fibrin, however, has been entertained by some eminent physiologists; and it does not seem right to allow the opinions of Wagner, Henle, and Wharton Jones to pass without notice, even though they appear to the writer to be easily set aside. By these observers, the elaboration of fibrin has been attributed to the *red* corpuscles, and has been regarded as one, at least, of their special functions. Nearly all the arguments, however, which have led us to assign this duty to the *white* corpuscles, tell equally *against* the doctrine now under consideration. The presence of fibrin in the circulating fluid may be regarded as a universal fact; but the red corpuscles are restricted to vertebrated animals: how, then, is the plastic element elaborated in the invertebrata? The number of *red* corpuscles in the blood of different classes bears an obvious relation to their amount of respiratory power, and to the *functional activity* of the several organs, which is closely connected with the amount of oxygen introduced into the system; but it does not bear the same relation with the activity of the *formative processes*, which may be taking place energetically (as in the developement of the embryo, or in the reparation of parts in the adult) in a state of functional quiescence. That the proportion of red corpuscles in the blood had a special relation to the nervous and muscular energy of an animal, and to the amount of oxygen consumed by it, has long ranked as a physiological truth; and the opinion has been gradually gaining ground, that although the liquor sanguinis is undoubtedly affected in a considerable degree by exposure to oxygen in the respiratory capillaries, the red corpuscles are the *special* agents by which oxygen is conveyed into the systemic capillaries, that it may furnish the conditions required for muscular contraction and other functional operations, which depend upon a due supply of *arterial* blood. In the invertebrated animals in general, the amount of respiration is so low, that this special provision is not required. There is an apparent exception, however, in the case of Insects, which have no red corpuscles, and which yet can display a greater amount of animal energy, and which consume (when in a state of activity) a larger quantity of oxygen in proportion to their size, than beings of any other class whatever. But here the exception proves the rule; for the conveyance of oxygen through the tissues is not accomplished in Insects by the circulating fluid, which has a comparatively sluggish movement, but is effected more directly by the ramifying tracheæ, which introduce air into the minutest portions of the structure.

The pathological evidence that the *red* corpuscles are *not* the elaborators of the fibrin, appears to the writer to be quite conclusive. Whilst the quantity of fibrin is so remarkably increased in inflammation, the number of red corpuscles undergoes no decided change. Again, the augmentation of the fibrin is not incompatible with a chlorotic state of the blood; the peculiar characteristic of which is a great diminution in the proportion of red corpuscles. By such alterations, the normal proportion between the *fibrin* and the red *corpuscles*, which may be stated as A : B, may be so much altered, as to become, in inflammation, 3A : B, in chlorosis A : $\frac{1}{4}$ B. Again, in fever, the characteristic alteration in the condition of the blood appears to be an increase in the amount of red corpuscles, with a diminution in the quantity of fibrin; yet if a local inflammation should establish itself during the course of a fever, the proportion of fibrin will rise; and this without any change in the amount of corpuscles. Lastly, the effect of loss of blood has been shown by Andral's investigations to be a marked diminution in the number of red corpuscles, with no decided reduction in the quantity of fibrin, even when this is much above its normal standard; and in this condition of the blood it has been observed by Remak that the colourless corpuscles are very numerous.

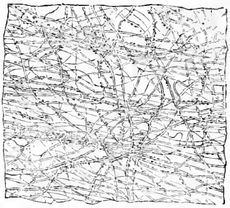
Formation of tissue.—With the elaboration of the alimentary materials into fibrin, the preparatory processes of nutrition may be regarded as terminating; since the next step is the transformation of this substance into organised tissue. Upon the mode in which this is effected, much light has been thrown by recent enquiries; but several points still remain obscure. We shall endeavour, in the following account, to distinguish what has been satisfactorily ascertained from what is merely hypothetical.

That the particles of perfectly-elaborated fibrin are capable, in solidifying, of spontaneously assuming a definite arrangement, cannot now be questioned. In the ordinary crassamentum of healthy blood, this arrangement can be seen, by examining thin slices under the microscope; especially after the clot has been hardened by boiling. A number of fibres, more or less distinct, may be seen to cross one another; forming by their interlacement a tolerably regular network, in the meshes of which the red corpuscles are entangled. This fact was known to

* Transactions of the Provincial Medical Association, 1843.

Haller; but it has been generally overlooked by subsequent physiologists, until attention was drawn to it by the enquiries of Messrs. Addison, Gulliver, and others. It is in the buffy coat, however, that the fibrous arrangement is best seen; on account, as it would appear, of the stronger attraction which the particles of fibrin have for one another, when its vitality has been raised by the increased elaboration to which it has been subjected. That there are varieties of *plasticity* in the substance, which, on account of its power of spontaneously coagulating, we must still call *fibrin*, appears from this fact among others,—that, in tuberculous subjects, the *quantity* of fibrin in the blood is higher than usual (Andral and Gavarret), although its plasticity is certainly below par. It is easy to understand, that its plasticity may be increased as that it may be diminished; and this either in the general mass of the blood, or in a local deposit. In fact, the *adhesions* which are formed by the consolidation of coagulable lymph,—or in other words, of liquor sanguinis, whose plasticity has been heightened by the vital actions of the white corpuscles in the capillaries of the part on which it has been effused,—often acquire very considerable firmness, before any vessels have penetrated them; and this firmness must depend upon that mutual attraction of the particles for one another, which in *aplastic* deposits is altogether wanting, and which in *caco-plastic* deposits is deficient. A very interesting example of a structure entirely composed of matted fibres, and evidently originating in the simple consolidation of fibrin, has lately been discovered by the writer. This is found in the membrane adherent to the interior of the egg-shell (membrana putaminis); and also in that which forms the basis of the egg-shell itself. Between the two, there is no essential difference; as may be seen by examining "an egg without shell," as it is commonly termed, (or rather one in which the shell-membrane has been unconsolidated by the deposition of calcareous matter); or by treating the egg-shell with dilute acid, so as to remove the particles of carbonate of lime, which are deposited in the interstices of the network. The place of the shell is then found to be occupied by a membrane of considerable firmness, closely resembling that which surrounds the albumen of the egg, but thicker and more spongy. After maceration for a few days, either of these membranes may be separated into a number of laminæ, each of which (if sufficiently thin) will show the beautiful arrangement of reticulated fibres, which is delineated in the accompanying figure (*fig.* 405). It is impossible to refuse to such a structure the designation of an *organised tissue*, although it contains no vessels, and must be formed by the simple consolidation of fibrin, poured out from the lining membrane of the oviduct of the bird. It is probably in the same manner, that the chorion of the mammiferous animal originates; since this is a new envelope, formed around the ovum, during its passage along the Fallopian tube. In the latter, for an ulterior purpose, vessels are afterwards developed, by extension from the contained ovum; and by the nutrition they supply, its size is increased, and changes take place in its texture. But in the egg-membrane of the bird, there is no need of vessels; because no subsequent change in its texture is required, and its duration is sufficient for the purpose it has to answer.

Fig. 405.



Membrane of egg-shell.

In all these instances, the fibrillated structure contains a certain amount of corpuscles, which lie in the meshes of its network. These have been termed "exudation-globules" by some authors,—by others "organic germs,"—and by others (especially Mr. Addison) are regarded as identical with the white corpuscles of the blood. They may present considerable varieties in size and appearance; having in some instances the characters of fully-formed cells, whilst in others they rather resemble nuclei or aggregations of granules. It seems difficult to believe, that they can be *identical* with the white corpuscles of the blood; since if the exudation has been poured forth by open orifices, sufficiently large to admit these to pass, there would be no obstacle to the escape of the red corpuscles,—at least where the latter are of smaller size, as in mammalia. They are probably to be regarded as originating in the fibrinous deposit, from germs which it contained, when effused from the vessels; of which germs the white corpuscles may have not improbably been the parents. The degree of their developement into cells would appear to depend upon the degree of plasticity of the deposit. Not unfrequently they seem arrested in their progress; especially in cases where the exudation verges towards a caco-plastic character. In the egg-membrane, very few of these corpuscles are seen; and as it is thus almost entirely composed of consolidated fibrin, it possesses considerable toughness. The same is the case with highly plastic exudations from inflamed serous surfaces. But in deposits which are less plastic, we see a larger number of these corpuscles, and a diminution and decreased tenacity of the fibres; the membrane then becomes quite friable, and approaches the character of a purulent exudation. The caco-plastic deposits will be presently noticed, under the head of *Abnormal States of Nutrition.* At present we shall proceed to consider the application of these facts to the ordinary conditions of that process.

The question naturally suggests itself, *in limine*, whether any of the tissues of the animal body are formed by the simple effusion of fibrin from the bloodvessels, and its subsequent consolidation in the manner already described. No such idea seems to have occurred to the continental physiologists, who, following in the path which had been marked out by Schwann, have sought to trace, for *all* the tissues, an immediate origin in cells. But the writer does not find that any of them are sufficiently aware of the facts already detailed, in regard to the definite structure which fibrin will assume, when it has undergone a high degree of elaboration, and has coagulated under the most favourable circumstances; and with the greatest respect to their authority, he ventures to attach sufficient weight to the observations of Messrs. Gulliver and Addison, confirmed as they are by his own, to induce him to adopt a different explanation, which he offers with diffidence, to be confirmed or set aside by future enquiries.

The fibrous tissue existing in false membranes, and still more that which has been discovered by the writer in the egg-shell, may be regarded in his opinion as a type of those *simple fibrous* tissues, which form a large porportion of the bulk of the body in the higher animals, and of which the function is purely mechanical. When we contrast the fabric of an animal with that of a plant, we are struck with this important difference in their conformation,—that whilst the latter is made up solely of elements which are to perform their several parts in the performance of the nutritive and reproductive operations, (the only exception being in the case of those more solid portions of the fabric which are destined to give mechanical support to the remainder),—the former is composed of a much greater variety of parts, which are adapted to *move upon* each other. Now this purpose requires, not only the addition of certain new tissues, to which nothing analogous is to be found in plants, for creating and exercising the motor power, but also an adaptation of the whole structure to this new condition. The tissues of plants entirely consist of *cells*, or simple modifications of them. Some of these cells being strengthened by internal deposits, form the solid woody framework of the stem and branches, which gives support to their wide-spreading foliage and numberless blossoms. Others coalesce, by the disappearance of their intervening partitions, into tubes, which serve for the conveyance of fluid between the most distant parts. But the great bulk of the fabric still consists of cells, closely adherent to each other, and actively participating in the various operations of organic life. In like manner in the animal body, a certain part of the cells have contributed to form the solid osseous and cartilaginous framework, which not only gives support and protection to the body, but contributes to its power of movement, by affording fixed points for the attachment of its muscles. Others again have coalesced into vessels, as in plants, for the rapid conveyance of fluids. Others, too, after a similar coalescence, have developed new and remarkable products in the interior of the tubes thus formed, and become transformed into those nervous and muscular tissues, to which nothing analogous is found in plants, and which are the peculiar instruments of animal life. Yet still there remains a large number of unchanged cells scattered through the body, which perform, as in plants, the essential part in the functions of nutrition, reproduction, &c. These, however, could not be held together in their constantly-varying relative positions without some intervening substance altogether different from *true cellular* tissue. It must be capable of resisting tension with considerable firmness and elasticity; it must admit free movement of the several parts upon one another; and it must still hold them sufficiently close together to resist any injurious strain upon the delicate vessels, nerves, &c., which pass from one to another, as well as to prevent any permanent displacement. Now all these offices are performed in a remarkably complete degree, by the *areolar* tissue,* the reason of whose restriction to the animal kingdom is thus evident. It is chiefly composed of interlacing fibres and shreds of membrane, which do not seem possessed of any other than simply *physical* properties; the small degree of vital contractility which it possesses in some spots (as in the dartos,) being attributable to the intermixture of fibres analogous to those of the unstriated muscular tissue. One of its most remarkable peculiarities is the rapidity of its regeneration; and this is obviously due, in part, to the large amount of bloodvessels by which it is traversed. The accounts given of its developement by Schwann and Henle do not by any means correspond; and it appears to the writer, that the evidence of the participation of cells in the process, in any other way than as elaborating the fibrin, is very insufficient. The observation already quoted from Mr. Addison (p. 746) seems to explain some appearances occasionally met with, which induced those observers to assign a more direct cell-origin to this tissue; for he notices that the remains of the white corpuscles, and little aggregations of the granules they had emitted, seemed to be the centres, as it were, of the fibrillation.†

If we once admit this doctrine in regard to areolar tissue, it is not difficult to extend it to those fibrous structures in general, which resemble it in the *physical* nature of their functions; and we shall then leave to the tissues of cell-origin, in animals as in plants, the performance of those operations which must be regarded as *vital* in their character. As an additional argument in support of this view, the appearances presented by the *semi-fibrous* cartilages may be adduced. In the cartilages of

* This was formerly termed CELLULAR tissue, under which designation it is described in the present work; but the appellation here given is the one under which it is now generally spoken of, for the sake of distinguishing it from tissues really composed of cells.

† Since writing the above, the author has become aware that a view of the developement of areolar tissue, essentially corresponding with that advanced above, has been recently put forth by Mandl, (Manuel d'Anatomie Générale, p. 552,) although *he* too seems quite unaware of the degree in which the fibrinous part of the blood *fibrillates* in coagulating.

the ribs, for instance, a more or less distinct fibrous appearance may be frequently seen in the intercellular substance; this is sometimes so faint, that it might be considered as an illusion, occasioned by the manipulation to which the section has been subjected; but it is often so well-defined, as almost to present the appearance of the true fibrous structure. No indication of the direct operation of cells in the developement of these fibres has ever been witnessed; and we can scarcely do otherwise than regard them as produced by the regular arrangement and consolidation of the particles of the *blastema* or plastic element, in virtue of its own inherent powers.

The production of the simple structureless membranes which exist in various parts of the body must be attributed, we think, to the consolidation of a thin layer of blastema, rather than to any metamorphosis of cells. The *basement* or *primary* membrane which lies beneath the epithelium of the mucous and serous membranes, and of the glandular prolongations of the former, as well as the membrane lining the bloodvessels, and bearing epithelium upon its inner surface, must probably be regarded in this light. It may be questioned, however, whether this is not to be regarded, in most cases at least, as a *transitional* form, rather than as a permanent structure. We have reason to believe that in many situations (as the lining of the alimentary canal and of its glandular prolongations,) the nuclei contained in this membrane must be continually developing themselves into epithelium-cells; and in some other instances it would seem, that a fibrous structure developes itself from it by a metamorphosis of a different kind. It is not difficult to imagine, that these variations may have their origin in the degree of plasticity of the element, of which the membrane was originally composed, and in the number of cell-germs which it includes. Considerable differences in the appearance of this primary membrane may be seen, in examining the residua left after dissolving away the calcareous matter of shells by dilute acid. Putting aside the *cellular* tissue which certain shells exhibit,* the most general animal basis of each layer is a very delicate membrane, which sometimes appears completely homogeneous, even when viewed with the highest powers of the microscope; but which in other instances presents a distinctly granular aspect, as if it consisted of a layer of molecules consolidated together by a structureless cement. These membranous films are included between strata of calcareous matter, poured out from the surface of the mantle, and thus undergo no change subsequent to their first production.

We have next to consider the mode in which the tissues, whose form is distinctly *cellular*, or which can be clearly proved to *originate in cells*, derive their nutriment from the blood. In the early stage of embryonic developement, as already stated, the whole fabric is composed of cells which present no recognizable differences amongst themselves, and which yet, by a process of histological transformation, become the elements of the different organs,—some of them still retaining the form of cells,—whilst others undergo changes which remove them altogether from that category. To the former class belong adipose tissue, pigment-cells, the various kinds of epithelium and epidermis, cartilage-cells, &c. Of the latter, the capillary bloodvessels, and the muscular and nervous tissues, are characteristic examples. Now there would seem much reason to believe, that in the regular process of nutrition, each of these tissues draws from the blood the materials necessary for its reparation and growth, as it does in the earlier stages for its first developement; and that the function of the blood is confined to the supply of these materials,—the germs of the new tissue being supplied by that previously existing. At any rate it may be safely affirmed that no evidence has been adduced which renders any other view probable. The self-nutrient power of the tissues is evinced by this fact among others,—that in no instance are their ultimate elements penetrated by the capillary bloodvessels. Thus although adipose tissue is traversed by a minute capillary network, the fat-cells lie in the meshes of this network, and are as independent of it, except as regards the supply of nutrient materials which they derive from it, as if they adhered closely to each other. The muscular fibres and nerve tubes, again, are not penetrated by capillary vessels, but are only surrounded by them. The connection of the cartilage-cells with the vessels is still more remote; for the true cellular cartilages are not penetrated by bloodvessels at all (in the healthy state at least), but are nourished by the imbibition of fluids from a plexus of dilated vessels that comes into relation with their external surface. We may infer, therefore, that the bloodvessels are subservient to the act of nutrition only by conveying the nutrient fluid into the neighbourhood where it is required,—just as, in the irrigation of a meadow, the water is carried in channels over the general surface, but has to find its way by percolation into the spaces between these;—and that it is by the materials which they derive from it that the several tissues are enabled to maintain their integrity, by reproducing their structure as fast as it is disintegrated. And it may not be unreasonable to infer that, in the very act of the death and disintegration of the parent structure, the germs of the new structures destined to replace it are set free, as happens in the reproduction of the simple cellular plants.

It may be doubted, however, whether the same holds good in regard to newly-forming parts, or with respect to the epithelium cells, which are formed on the free surface of the basement membrane, and which are cast off without reproducing themselves. These last seem to originate in germs contained in the subjacent membrane, and a continual supply of such germs must therefore be required. It can

* See a paper by the author on the Microscopic Structure of Shell, in Annals of Natural History, December, 1843.

scarcely be doubted, therefore, that these are supplied directly from the blood. Dr. Barry and Mr. Addison have spoken with much confidence of the *metamorphosis* of the white corpuscles of the blood into epithelium-cells; but that this idea is totally inadmissible is proved by the existence of a continuous stratum of basement-membrane, between the capillary network and the epidermic or epithelial layer. It is not impossible, however, and perhaps may be considered probable, that the cell-germs contained in this basement-membrane, from which the cells on its external surface appear to take their origin, may be the offspring of the white corpuscles of the blood, which thus supplies both the plastic materials and the germs of the constantly-forming new crops of epithelial cells. There is no other tissue in the body, after all its organs had attained their full developement, which can be regarded as taking its origin from the blood in the same degree; but it may be questioned whether in the formation of new parts, either during the developement of the embryo, or in the reparation of injuries, the office of the blood is not of a similar duplex character. Thus when plastic lymph is thrown out, between the two surfaces of a wound, the first process, as already mentioned, is its fibrillation; but at the same time a developement of cells takes place in it, which cells may possibly undergo a subsequent metamorphosis into the various forms of tissue which the newly-formed part afterwards contains, precisely as in the first developement of the embryonic structure. Such a view, at least, would seem probable in regard to the capillary vessels, which seem to be formed at least as much by the inherent powers of the coagulum, as by the extension of the vessels from the subjacent surface.

These views are thrown out as hints, rather than as settled ideas. It would be premature, in the present state of our knowledge, to attempt to decide questions of such importance without much further examination; and we can only attain a balance of probabilities by interpreting the insufficient results of observation by the aid of the best analogies we can find. The whole subject has made immense progress during the few years which have elapsed since the commencement of the present work; but here, as elsewhere, retardations have occurred through hasty generalization and dogmatic assumptions; and much patient, well-directed, sagacious observation will be needed to unravel the many intricate questions that yet remain to be solved.

Varying activity of the nutritive processes.—Without any change in the *character* of the nutritive processes which we have been describing, there may be considerable variations in their *degree of activity;* and this, either as regards the entire organism or individual parts, though most commonly the latter. These variations may be so considerable as to constitute disease; though there are some which take place as part of the regular series of physiological phenomena. Thus the nutritive processes should have a degree of activity more than sufficient to supply the waste of the body during the whole period of infancy, childhood, and adolescence, until, in fact, its full dimensions are attained; whilst, on the other hand, they are usually less rapid than the disintegrating processes in old age, so that the bulk of the body diminishes. Now as the waste of the body, so far from being *more* rapid in old age than in childhood, is much *less* so, it follows that the difference in the activity of the nutritive processes in these two states must be very considerable; and this is manifested, not only in the greater demand for food which exists in the child (relatively to the bulk of its body), but also in the greater quickness and facility with which injuries are repaired. Local variations may also occur as part of the regular train of vital actions in the adult; thus we perceive an enormous increase in the amount of tissue contained in the uterus and mammary glands during pregnancy, and a decrease in the bulk of the thymus gland after the first year of infancy. Now in these cases we see that increased nutrition is invariably connected with increased functional activity, and diminished nutrition with diminished functional activity: and this we shall find to be the constant rule in regard also to those variations which must be considered as abnormal.

Increased nutrition, or *hypertrophy*, is never known to affect the *whole* body to a degree sufficient to constitute disease. It cannot be produced as a consequence of the ingestion of an undue supply of food, for this does not increase the formative activity of the tissues, but merely renders the blood richer in nutritive materials, a part of which the excreting organs are called on to be continually removing, without its being rendered subservient to the wants of the body; whilst another part may be employed in the nutrition of one particular tissue, the adipose, which has a tendency to increase with the superfluity of non-azotized food, provided that the requisite amount of cellular tissue be generated to hold the fatty matter. But examples of hypertrophy of particular tissues or organs are very common. Thus any particular set of muscles which is subjected to frequent and energetic use acquires a great increase in bulk, as we see in the arms of a blacksmith or waterman, the legs of an opera-dancer, &c. The hypertrophy of *these* muscles is a consequence of their increased functional activity, which being produced by an exertion of the will, and unaccompanied with any injurious effects on the system, can scarcely be regarded as morbid. But there are many instances in which the involuntary muscles acquire a greatly-increased strength, in consequence of an obstruction to their action which results from disease. Thus we see the right ventricle of the heart become hypertrophied (and dilated at the same time) where chronic pulmonary disease produces a difficulty in the propulsion of the blood through the vessels of the lungs; the muscular fibres of the bladder become enormously hypertrophied, when stricture, diseased prostate, or other causes produce a demand for increased expulsive force on the part of the bladder; and those of the stomach also become so in cases of stricture of the pylorus. As an instance of hypertrophy of a secreting organ in consequence of an undue excitement of its function, we may notice the enlargement which usually takes place in the kidney, when its fellow is incapacitated by disease. And the nervous system presents us with a very remarkable case of hypertrophy of a part resulting from over-excitement of its function; for if young persons who naturally show precocity of intellect are encouraged rather than checked in the use of their brain, the increased nutrition of the organ (which grows faster than its bony case) occasions pressure upon its vessels, it becomes indurated and inactive, and fatuity and coma are the result. Local hypertrophy may be induced also by local congestions; but in such cases it will usually be found that the form of tissue produced is of the lowest kind, unless the functional activity of the part be increased by the congestion. Thus when disease of the heart produces long-continued congestion of the lungs, liver, spleen, &c., the bulk of these organs increases; but chiefly by the production of an additional amount of interstitial areolar tissue, which may result (as we have seen) from the simple consolidation of fibrin; and partly also (in the case of the spleen especially) by the gorging of their distensible veins with blood.—One of the least explicable cases of hypertrophy is that which takes place in the thyroid gland, causing bronchocele. So little is known of the normal office of this organ, that it cannot be determined whether its increased size be due to an increased activity of its functional operations, or to an unusual formative activity in its tissue, depending on some hidden cause. The connection of this disorder with causes which affect the whole constitution, rather than individual parts, would seem to indicate the former.

When the waste of the tissues is more rapid than their replacement by nutrition, *atrophy* is said to take place; and this may affect either the whole body, or individual parts. General atrophy, marasmus, or emaciation, may result from an insufficient supply of plastic matter, from want of formative power in the tissues themselves, or from their too rapid disintegration. The insufficiency of the supply of nutritive matter may depend either on deficiency in the azotized substances ingested as food, or on imperfect performance of those processes by which they are converted into the plastic element,—fibrin. Hence, even when there is an ample supply of food, atrophy may take place to a very severe extent, in consequence of disordered digestion, or of want of vital power in the fibrin-elaborating cells. Again, we have reason to believe that the formative power in the tissues themselves may be diminished, so as to check the process of nutrition, even when the plastic material is supplied; thus there seems to be a complete stoppage of this action in fever, and a diminution of it in that irritable state of the system, which results from excessive and prolonged bodily exertion or anxiety of mind, especially when accompanied by want of sleep. It is difficult to separate this cause, however, from mal-assimilation on the one hand, or too rapid decay of the tissues on the other: for we know that, in such states, there is a tendency to imperfect elaboration of the fibrinous element, and at the same time an unusually rapid disintegration, as manifested by the increased amount of urea in the urine. The influence of excessive waste in causing atrophy of the body is well shown in the cases of diabetes mellitus and colliquative diarrhœa; for in both these, the increase and depravation of the secretions are undoubtedly to be regarded as the effects, and not the causes, of the textural changes with which they are associated. Colliquative diarrhœa is a constant occurrence on the last day or two of life in animals reduced by starvation, and is accompanied by that fœtid odour of the body, which indicates that decomposition is already going on throughout the system. The same thing occurs as the ordinary termination to many diseases of exhaustion; in which inanition is unquestionably the immediate cause of death. Partial atrophy may occur in consequence of disuse of the organ affected, occasioning inactivity in its formative processes; or as a result of a deficiency of nutriment, occasioned by an obstruction to the circulation. Of the operation of the former cause we have many examples in the ordinary processes of the economy. Thus the uterus is atrophied, relatively to its previous condition, as soon as parturition has taken place; and the mammary glands, when lactation has been discontinued. It is probably in part to this cause, and in part to the diversion of the blood into other channels, that we are to attribute the atrophy of many parts, as the developement of the system advances, which at an earlier period were of large comparative size,—such as the corpora Wolffiana, the suprarenal capsules, and the thymus gland. Many instances might be adverted to, of the influence of suspension of functional activity, as a result of disease or injury, in producing local atrophy. One of the most common cases is the atrophy of muscles which is consequent upon their disuse. This disuse will produce the same effect, whether it be occasioned by paralysis, which prevents the nervous centres from exciting the muscles to contraction; or by anchylosis, which interposes a mechanical impediment to their use; or by fractures or other accidents, the reparation of which requires the limb to be kept at rest. Or even if, without having suffered from any injury, a limb be fixed during some time in one posture, its muscles will become atrophied, as is seen in the case of the Indian fakirs. It has been shown by Dr. J. Reid, that the atrophy of the muscles, and their consequent loss of contractility, is not to be imputed to the withdrawal of nervous influence, in any other way than as producing cessation of their activity; for he found that, when the muscles of one leg of a frog, both whose crural nerves had been divided, were daily exercised by galvanism, they retained much more of their usual size and firmness than those of the leg which was left at rest. A case has fallen under the writer's observation, in which *both* limbs were affected with almost complete (hysteric) paraplegia; but one was also frequently seized with violent cramps, from which the other was free; the difference in the muscularity of the two limbs was very striking, and was evinced by the greater circumference of the one affected with cramps (which was an inch and a half larger round than the other), as well as by its greater firmness of flesh. Similar facts may be adduced, in regard to atrophy of nerves, from interruption of their normal function. Thus when the cornea has been rendered so opaque by accident or disease, that no light can penetrate to the interior of the eye, the retina and the optic nerve lose, after a time, their characteristic structure; so that scarcely a trace of the peculiar globules of the former, or of the nerve-tubes of the latter, can be found in them. These and similar facts are readily understood, when connected by the general principle formerly laid down,—that every proper *vital* operation involves an act of nutrition; in such a manner that, whilst the vital properties of any part are dependent upon its due nutrition, the amount of its nutrition will in return depend upon the degree in which these properties are exercised.

Partial atrophy may depend, however, upon causes of a purely mechanical nature; such, for example, as produce an interruption of the current of blood through the part. This may result from changes in the arteries supplying it, such as ossification, or other forms of obstruction. Or it may be consequent upon disease in the part itself; as when the deposits produced by inflammation tend to contract, and thus to press upon the vascular structure, which frequently happens in the lungs, liver, and kidneys; or when the inflammation occurs in the vessels themselves, causing adhesion of their walls, and obliteration of their tubes; or when a new growth absorbs into itself all the nutritive materials which the blood supplies.

Abnormal forms of the nutritive process.—Under the preceding head we have considered the chief variations in the degree of activity that are witnessed in the ordinary or normal conditions of the nutritive process,—that is, those conditions in which the products are adapted by their similarity of character to replace those which have been removed by disintegration. But we have now to consider those forms of this process, in which the products are abnormal,—being different from the tissues they ought to replace. We shall confine ourselves to a brief examination of the two most important of these states;—that which is termed inflammation, and that which gives rise to tubercular deposit. The former results from an *excess* of the plastic element in the blood: the latter from a *depraved* condition of it, whereby its plasticity is impaired or destroyed.

Notwithstanding all the attention which has been given to the state of the *vessels* in inflammation, a careful consideration of its phenomena, with the light which recent investigations have thrown upon these, leads us to attach comparatively little importance to this, and to seek for the essential character of the process elsewhere. The researches of Addison, Williams, Barry, Gulliver, Andral, and others, all seem to point to the following conclusions.—1. That there is a peculiar afflux or determination of the white corpuscles of the blood towards the inflamed part. 2. That the total amount of these corpuscles in the circulating blood undergoes a great increase. 3. That the quantity of fibrin in the blood augments in proportion to the extent and intensity of the inflammation; and this even when it was previously, from the influence of some other morbid condition, below the usual standard. With its quantity, its plasticity or tendency to organization also increases in a healthy subject. Now when these facts are compared together, and are connected with those formerly adduced, in regard to the probable function of the white corpuscles of the blood, they lead almost irresistibly to the conclusion, that the process of inflammation essentially consists in an undue stagnation of the white corpuscles of the blood in the vessels of the part, an excessive multiplication of these by the ordinary process of generation, and a consequent over-production of fibrin. By these changes, and by the results which follow them, inflammation may be distinguished from the various forms of hyperæmia and congestion. To the results, then, we shall next direct our attention.

It may be inferred, we think, from various phenomena, that whilst the formative power of the *blood* is increased in inflammation, that of the *tissues* is diminished. Certainly this is the case in regard to the system at large, when febrile irritation has been established; for, notwithstanding the increased plasticity of the blood, we see the body wasting, instead of increasing in vigour. And it may be inferred, also, in regard to the tissues of the part affected, from the tendency to atrophy and disintegration which they exhibit; and which is greater (leading even to the death of whole parts) in proportion as the inflammation is more intense, and as the tendency to the deposit of new products is the more decided. That a stagnation of blood takes place in the vessels of the inflamed part is another general fact, which throws some light upon the nature of the process; for this stagnation is obviously favourable to the transudation of the fluid plasma of the blood, through the walls of the vessels, into the surrounding tissue, or upon a neighbouring surface. This deposition of the fibrinous element, possessing a high degree of plasticity, and capable of spontaneously passing into simple forms of tissue (which may be gradually replaced by higher forms, when penetrated by vessels from the surrounding parts), may be regarded as the first characteristic result of inflammation. That this deposition of the fibrin, which has accumulated to an unusual extent in the blood, should take place *only* in the inflamed part, cannot perhaps be very readily accounted for; but we see that, when the inflammatory diathesis is once established,—or, in other words, when the quantity of fibrin in the circulating part is much increased,—local inflammat.ons will be excited by very trifling causes (at other times quite inoperative), which are followed by the same results as the original one.

But it frequently happens that the fibrinous element of the blood, though increased in quantity, does not possess its normal plasticity; and the deposits which are the consequence of its effusion are far from being as organizable as in the preceding case, and are either imperfectly organizable, or *caco-plastic*, or altogether unorganizable or *aplastic*. The tendency to such deposits may arise from various causes. Thus, when the inflammation is from the first of a low or asthenic character, or when the blood is previously in an unhealthy condition (as, for instance, when there is a deficiency in the number of red particles, the presence of the normal amount of which seems important to the complete elaboration of the fibrin), no other kind of deposit takes place from the first; and even when organizable plasma has been copiously thrown out in the first instance, it is not unfrequently succeeded by caco-plastic, or aplastic products,—either from a change in the character of the inflammatory process itself,—or because the late products are thrown out in such a position as to be cut off from that influence of living surfaces around, which is necessary to their complete organization. Between the organizable or *euplastic*, and the *caco-plastie*, and *aplastic* deposits, the gradations are almost insensible. The cells and fibres which are characteristic of the first diminish in number and are less perfectly formed; and they are replaced by a granular amorphous matter, which possesses but little cohesion, and which, being totally incapable of entering into any form of tissue, acts as a foreign body, and becomes a source of irritation. The limited space allotted to this subject prevents any more particular description of these products from being here given; but there is one which must not be overlooked, since its occurrence is very frequent, its effects upon the system most important, and its character very peculiar. The product alluded to is *pus*. This is characterized by the presence of a number of cells of a peculiar aspect, having a very tuberculated or mulberry surface, which are seen floating in a fluid, termed *liquor puris*, which is of an albuminous or low fibrinous character, being entirely destitute of organizability. Now the production of pus in an inflamed part, or in other words, the act of suppuration, may be due to one of three causes, viz.,—the intensity of the inflammation; the presence of air, which becomes a source of irritation; and a previously vitiated state of the blood. Various attempts have been made to show that the pus-globule is a degenerated red or white corpuscle of the blood; but it seems more probable, however, that it does not escape from the vessels as a complete cell, but as a cell-germ, which may have had its origin in a white corpuscle of the blood; and which, under favourable circumstances, might have produced an exudation-corpuscle. At any rate, it must be regarded as a *degenerated* form of cell; and the *liquor puris* must be considered as analogous to the plasma of the blood in a degenerated state.*

In what manner the inflammatory process determines the formation of the pus cell, and the consequent degradation of the product, we are at present unable to state; but that the degree of irritation in the part has an influence upon it is evident from the effects of the contact of air upon inflamed surfaces, causing those elements to take the form of pus, which would otherwise have been thrown out as a plastic deposit. This circumstance would seem to indicate, beyond all doubt, that the exudation and pus-corpuscles, the plastic lymph, and the aplastic *liquor puris* have the same origin, but that their character is determined by local circumstances. There is great reason to believe, that when pus is introduced into the blood, it may induce such a change in the character of the fluid, as speedily to impair its vital properties; so that the pus-corpuscles will rapidly propagate themselves in the blood, and the plasticity of the liquor sanguinis will be diminished. In this manner the whole system will be seriously affected, and there will be a tendency to deposits of pus in various organs—especially those which, like the lungs and liver, serve as emunctories to the system—without any previous inflammatory changes in these parts.

The last form of disordered nutrition which we shall consider is that which takes place in the *tuberculous* diathesis, and which is marked by the deposition of tubercular matter, in place of the normal elements of tissue, both in the ordinary process of nutrition, and still more when inflammation is set up. From an examination of the blood of tuberculous subjects it appears that the fibrinous element is not deficient in amount, but that it is not duly elaborated, so that the coagulum is loose, and the red corpuscles are found to bear an abnormally low proportion to it. We can understand, therefore, that such a constant deficiency in plasticity must affect the ordinary nutritive process; and that there will be a liability to the deposit of caco-plastic products, without inflammation, instead of the normal elements of tissue. Such appears to be the history of the formation of tubercles in the lungs and other organs, when it occurs as a kind of metamorphosis of the ordinary nutritive process; and in this manner it may proceed insidiously for a long period, so that a large part of the tissue of the lungs shall be replaced by an amorphous deposit, without any other ostensible sign than an increasing

* It would not seem improbable that the *liquor puris* is the product of the action of the pus-corpuscle, in the same manner as we have endeavoured to show that the *liquor sanguinis* is the result of the elaborating action of the colourless corpuscles of the blood. This idea seems confirmed by the observation of Mr. Gulliver, that the *pyogenic* membrane which lines the cavity of an abscess, and from which the fluid appears to be secreted, is chiefly composed of cells that bear a strong resemblance, on the one hand to the pus-corpuscles, and on the other to the colourless corpuscles of the blood; these cells are held together by fibrinous fibrils.

difficulty of respiration. It is in the different forms of tubercular deposit that we see the gradation most strikingly displayed between the euplastic and the aplastic formations. In the semi-transparent, miliary, grey, and tough yellow forms of tubercle, we find traces of organization in the form of cells and fibres, more or less obvious; these being sometimes almost as perfectly formed as those of plastic lymph, at least on the superficial part of the deposit, which is in immediate relation with the living structures around, and sometimes so degenerated as scarcely to be distinguishable. In no instances do such deposits ever undergo further organization, and therefore they must be regarded as *caco-plastic*. But in the opaque, crude, or yellow tubercle, we do not find even these traces of definite structure; for the matter of which it consists is altogether granular, more resembling that which we find in an albuminous coagulum. The larger the proportion of this kind of matter in a tubercular deposit, the more is it prone to soften, whilst the semi-organized tubercle has more tendency to contraction.

Fig. 406.*

Microscopic appearances of tubercular matter in the lungs, after Gulliver.

To the left, magnified 190 diameters, is shown a central portion of tubercle, from the lungs of a man aged 22, who died of pulmonary consumption; the tubercle is contained in the air-cells, and surrounded by the fibres of their walls. To the right is depicted some of the same tubercle, separated and magnified about 820 diameters.

Now although tubercular matter may be slowly and insidiously deposited, by a kind of degradation of the ordinary nutritive process, yet it cannot be doubted that inflammation has a great tendency to favour it; so that a larger quantity may be produced in the lungs, after a pneumonia has existed for a day or two, than it would have required years to generate in the previous mode. But the character of the deposit still remains the same; and its relation to the plastic element of the blood is shown by the interesting fact, of no unfrequent occurrence,—that, in a pneumonia affecting a tuberculous subject, plastic lymph is thrown out in one part, whilst tubercular matter is deposited in another. Now inflammation, producing a rapid deposition of tubercular matter, is peculiarly liable to arise in organs which have been previously affected with chronic tubercular deposits, by an impairment of the process of textural nutrition; for these deposits, acting like foreign bodies, may of themselves become sources of irritation; and the perversion of the structure and functions of the part renders it peculiarly susceptible of the influence of external morbific causes. These views, at which several recent physiologists and pathologists have arrived on independent grounds, seem to reconcile or supersede all the discordant opinions which have been upheld at different times regarding the nature of tubercle, and lead to the soundest views with respect to the treatment of the diathesis.

* From Wagner's Physiology, p. 360.

Parasitic growths.—Besides the products of disordered nutrition, which have been just considered, there is another class of morbid structures, differing from the preceding in well-marked and important characters. Their existence and mode of growth cannot generally be traced to simple variations in the local circulation and in the formative powers of the parts affected; and they enjoy an *independent* vitality, which causes their maintenance and increase to be influenced but little by the state of the textures around, except so far as this may affect the supply of blood which they receive. They bear a certain resemblance to other tissues, in an early stage of the developement of the latter; being for the most part composed of cells and fibres, combined in different modes: and they also correspond with them in chemical constitution. It is by this last character, indeed, that they are to be distinguished from the vegetable organisms, which are unquestionably developed occasionally in the living animal body, and which often closely resemble them in aspect. The best practical division of parasitic growths is into the *non-malignant* and the *malignant*;—the former being of local origin, not tending to reappear in distant parts of the body, and having no injurious effect upon the surrounding tissues, except by the pressure they may exercise upon them, or the nourishment they may withdraw;—whilst the latter, having once made their appearance in the body, tend to reappear at distant parts (even after the original growth has been removed), induce a complete change of structure and of actions in the organs in which they are developed, and exert a very depressing influence upon the bodily system at large.

The *non-malignant* growths may present various characters, intermediate between those of the tissues they replace, and those of malignant structures. In regard to their pathological cause, " we cannot at present go beyond the supposition, that they arise from altered vital properties in some of the molecules of the textures in which they are developed; so that, instead of being assimilated to these textures, and conforming to the laws of their growth and decay, these molecules grow of themselves in modes more or less peculiar, and more or less independently of the influences of the adjoining living parts. Where these modes are less peculiar, and more dependent upon the nutrition of the adjacent structures, the growths are less abnormal, vary less from these structures, and more resemble either hypertrophy or euplastic deposits; and they do mischief rather from their size and situation than from their intrinsic nature. Where the mode of growth is more peculiar, and more independent of that of the textures in which they arise, the resulting tumours are more abnormal in their nature and mode of developement; they approach in character to malignant diseases, acting injuriously, not only by their bulk and position, but also by abstracting the nourishment of the body, and tending to supersede the natural structures."*

Among the *malignant* growths, too, there are various shades or degrees of malignancy; one or more of the characters just now assigned to them being either absent or imperfectly developed. Thus there are certain growths which have a tendency to spread through the system, and even to propagate themselves from one individual to another, and which agree with true malignant growths in being composed, like them, of cells having a tendency to rapid multiplication, but which yet exert no serious influence upon the general constitutional state, and which cannot, therefore, be properly termed malignant: such are *molluscum* and *porrigo favosa*. And in other instances we meet with large tumours, producing a very injurious effect upon the surrounding textures, and exerting a very serious influence upon the system at large; the malignancy of which, however, is doubtful, because they show no tendency to reappear in other parts of the body. The origin of all these growths is involved in great obscurity; but there does not appear to the writer to be anything so *specific* in their character as to require the supposition that their germs are introduced into the body from without. It is true that when they have once established themselves they may be propagated by inoculation, which transplants some of the cells or cell-germs into a new locality; and the appearance of the disease in parts of the same body distant from those which were first affected, is probably due to the diffusion of the germs by the current of the circulation. But this power of reproduction is by no means limited to malignant growths, since it belongs to all cells at a certain stage of their developement. And, as Dr. W. Budd† has remarked, the causes which have been supposed to induce cancer are not such as can, in any intelligible way, favour the introduction of germs from without the body. Thus in chimney-sweeps and others the continued application of soot has been observed to be followed by the occurrence of cancer in the scrotum in such a number of cases, as to justify the inference that it has been the exciting cause; and the often-repeated contact of a tobacco-pipe with the lip has also been considered a cause of cancer of that part. But neither of these causes can in any conceivable way promote the developement of cancer from extrinsic germs. We are quite in the dark, however, as to the mode in which any perversion of the ordinary nutritive processes arising from external irritation of whatever kind, can give rise to structures so peculiar in their nature and history as are the various forms of cancerous growths. For a detailed account of their characters as unveiled by recent microscopic researches, the reader must seek elsewhere; since all that we can here attempt is to give a general idea of their peculiar nature. (See Products, Morbid.) The greater part of every true malignant growth is made up of cells, which, instead of undergoing transformation into other kinds of tissue, continue in their original state, and enjoy the power of rapid multiplication. In the harder forms of cancer the masses of cells are traversed by bands of solid fibrous texture, and such are of slow growth, and may remain with but little change for many years, apparently because the pressure to which they are subjected prevents their rapid increase. But the softer forms are composed almost entirely of cells, and these of the most rapidly multiplying character; so that, in the rapidity with which they shoot up, they remind us of the vegetable fungi. Now the influence of either of these forms of morbid growth upon the constitution is very decided, and distinguishes them from non-malignant structures; but this is more evident, the more *time* is afforded for the manifestation of their effects. It is evident even from the appearance of the subject of them that the blood must be in a very depraved state, for there is a peculiar dirty sallowness about the complexion which is seen in no other disease; the emaciation reaches a point unequalled under any other circumstances; and accidental injuries which may occur during the progress of the malady are but very imperfectly repaired. In their deleterious effects upon the character of the circulating fluid, therefore, we may not improperly compare cancer-cells with pus-globules.

General summary.—From what has been stated it appears evident, that the process of nutrition essentially consists in the growth of the individual cells composing the fabric; and that these derive their support from the organic compounds with which they are supplied by the blood, just as the cells composing the simplest plants derive theirs from the inorganic elements which surround them. And as different species of the latter select and combine these in such modes and proportions as to give rise to organisms of very diversified forms and properties, so is it easily intelligible that the different parts of the fabric of the highest animals, whether normal or abnormal, should exercise a similar selective power, in regard to the materials with which the blood supplies them. The structure composing every separate portion of the body has what may be termed a *special* or *elective* affinity for some particular constituents of the blood; causing it to abstract from that fluid and to convert into its own substance certain of its elements: and this is exercised not only in regard to the normal constituents of the blood, but also towards morbid matters which may be circulating with it. Of the causes which enable the cells of animal or

* Williams's Principles of Medicine, § 574.
† Lancet, May 28, 1842.

vegetable structure to exercise these varied attractions, our knowledge is at present very limited. It will probably long remain an ultimate fact in physiology that cells have the power of growing from germs, of undergoing certain transformations, and of producing germs that will develope other cells similar to themselves, just as it is an ultimate fact in physics that masses of matter attract each other; or in chemistry, that the molecules of different substances have a tendency to unite, so as to form a compound different from either of the elements. It is of such ultimate facts that the science of vitality essentially consists. The conditions under which the assimilating power operates are, however, like the laws of chemical affinity, freely open to our investigation; and it is a great step in the progress of the inquiry to become aware that these are so closely conformable throughout the organized world, as we have endeavoured to show them to be.

It may be stated as a general fact, that in assimilating or converting into its own substance matter which was previously unable to exhibit any of the manifestations of life, every cell thereby participates in the process of organization and vitalization; for by the new circumstances in which the matter is placed its sensible properties are altered,—some which were previously dormant being now caused to manifest themselves, whilst others, which were previously evident, become latent. No matter that is not in a state of organization can exhibit these properties, which, from their being peculiar to living bodies, and altogether different from those of which physics and chemistry take cognizance, are termed *vital;* and it may also be asserted that no matter which exhibits perfect organization is destitute of the peculiar vital properties belonging to its kind of structure. (See Life.) Hence every act of nutrition is, in fact, the creation of a new amount of vital force; and when that vital force has been expended, no more can be developed except by the nutritive process.

From the foregoing details it further results that we must regard each part of the organism as having an *individual* life of its own, whilst contributing to uphold the *general* life of the entire being. This life, or state of vital action, depends upon the due performance of the functions of all the subordinate parts which are closely connected together. The lowest classes of organized beings, and even the highest at an early stage of their embryonic developement, are made up of repetitions of the same elements; and each part, therefore, can perform its functions in great degree independently of the rest. But in ascending the scale or in tracing the advancing developement of the embryo, we find that the individual lives of the cells become gradually merged (so to speak) in the general life of the structure; for they become more and more different from each other in function, and therefore more and more dependent on each other for their means of support; so that the activity of all is necessary for the maintenance of any one. Hence the interruption of the function of any important organ is followed by the death of the entire structure; because it interferes with the elaboration, circulation, and continual purification of that nutritious fluid which supplies the pabulum for the growth and reproduction of the individual cells. But *their* lives may be prolonged for a greater or less duration after the suspension of the regular series of their combined actions; hence it is that *molecular* death is not always an immediate consequence of *somatic* death. (See Death.) But if the function of the part have no immediate relation to the indispensable actions just referred to, it may cease without affecting them; so that molecular death may take place to a considerable extent without somatic death necessarily resulting.

The foregoing considerations have a very important bearing on the question of the degree to which the process of nutrition is under the influence of the nervous system, a question on which, as it appears to the writer, very erroneous ideas have been commonly entertained. For it has been customary to speak of this process (as well as of secretion) as *dependent* upon nervous agency; or, in other words, to assert that the nervous system is not only the instrument of the functions of animal life, but is also the *primum mobile* of the organic operations. Now the independent properties of the cells in which all organized tissues originate, might be of itself a satisfactory proof that in animals, as in plants, the actions of nutrition are the results of the powers with which they are individually endowed; and that whatever influence the nervous system may have upon them, they are not in any way essentially dependent upon it. Moreover there is an evident improbability in the idea "that any one of the solid textures of the living body should have for its office to give to any other the power of taking on any vital actions;" and the improbability becomes an impossibility, when the fact is known, that no formation of nervous matter takes place in the embryonic structure, until the processes of organic life have been for some time in active operation. The influence which the nervous system is known to have on the function of nutrition may operate in several ways. Thus, if the nerves proceeding to any set of muscles be divided, those muscles will be atrophied in consequence of the cessation of their activity, as already explained. In other instances we may not improbably regard the influence of the nervous system to be exercised through the medium of its controlling power over the diameter of the bloodvessels, by which it may govern the afflux of blood. And there can be little doubt that, in some manner yet unexplained, the nervous system exerts an influence over those preliminary processes, by which the plastic element of the blood is elaborated; so that long-continued anxiety or depression of mind may produce general atrophy, or a tendency to tuberculous deposit. It appears to be invariably through *emotional* states of the mind that the nutritive process is affected; the *will* not possessing any direct power of influencing them. But there can be no doubt that the continual voluntary direction of the attention to the sensations of any part, giving rise to emotions on which the mind frequently dwells, may so far modify the nutrition of the part as to become a cause of diseased action in it. All these facts, however, point rather to the *influence* which the nervous system possesses over the organic functions, than to the dependence of these upon its agency; and it may be safely asserted that no such proof of its more direct influence, as is required to counterbalance the manifest improbability which has been shown to attend it, has yet been given. Some additional considerations upon this important subject will be offered under the head of SECRETION.

(*W. B. Carpenter.*)

ŒSOPHAGUS. (Οἴω, I carry, and φαγω, I eat.)—Gr. οἰσοφάγος; Fr. *œsophage;* Ital. *gola;* Germ. *Speiseröhre.* The œsophagus is that portion of the alimentary canal which intervenes between the inferior extremity of the pharynx and the cardiac orifice of the stomach. It occupies the lower part of the cervical region, traverses the thorax, and enters the abdomen.

Direction.—The direction of the œsophagus is nearly vertical; in the cervical region it deviates slightly to the left; in the upper part of the thorax it inclines somewhat to the right, and in the lower part of the same region it is again directed to the left, so as to occupy the median line during its passage through the diaphragm.

Dimensions.—The œsophagus is not of uniform diameter throughout its entire length. In the neck it is narrower than in any other region; it consequently happens that a morsel of food too large to pass readily along the œsophagus, is usually arrested immediately after it has been transmitted from the pharynx. In its upper part the œsophagus is somewhat flattened and compressed in the antero-posterior direction, but its inferior portion is more or less cylindrical, and presents the appearance of a rounded cord.

Relations.—The œsophagus has many important relations, which may be considered successively in the cervical, thoracic, and abdominal regions. In the cervical region it corresponds anteriorly to the membranous part of the trachea, with which it is connected by some intervening cellular tissue: in the lower part of the neck where it deviates to the left it comes in contact anteriorly with the left sterno-thyroid muscle, the thyroid gland, the inferior thyroid artery, and the left recurrent nerve. Posteriorly it has the cervical vertebræ and the longus colli muscle, with which it is connected by means of loose cellular tissue, so that free movement of the œsophagus upon the spine is allowed during the process of deglutition. Laterally it is in relation with the thyroid body, with the common carotid arteries, and more externally with the vagi nerves and the internal jugular veins. In consequence of the œsophagus deviating slightly to the left in the lower part of the neck, its relations are somewhat different on the two sides. Thus the left common carotid is in closer relation with the œsophagus than the right. The left recurrent nerve is anterior to the œsophagus, while the right is somewhat posterior.

The *thoracic portion* of the œsophagus is placed in the posterior mediastinum. It corresponds anteriorly to the trachea, and immediately below the bifurcation of the trachea to the left bronchus, which crosses it obliquely, to the arch of the aorta, to the left subclavian and carotid arteries, and to the base of the heart, from which it is separated by the pericardium. Posteriorly it has the spine, with which in the upper part of the chest it is in close contact; but as it descends it becomes separated from the spine by cellular membrane, by the right intercostal arteries, by the vena azygos, and by the thoracic duct, which in the lower part of the chest is on the right of the œsophagus, but ascending it passes behind and above is placed on its left side. At the inferior part of the thorax, immediately before passing through the diaphragm, the œsophagus has behind it the thoracic aorta. Laterally it has on its left the aorta, and on the right side the pleura forming the right layer of the posterior mediastinum. It is accompanied by the two vagi nerves, one on each side, which send numerous filaments from one to the other, and thus form the plexus gulæ; at the lower part of the chest the left vagus nerve becomes somewhat anterior, and the right posterior. This portion of the œsophagus is surrounded by a considerable quantity of loose cellular tissue and by several lymphatic glands.

The abdominal portion of the œsophagus is very short, and has no relations of importance. After passing through the diaphragm it is covered both anteriorly and posteriorly by the peritoneum. It also comes into contact anteriorly with the left lobe of the liver. Without depressing the stomach and elevating the diaphragm this portion of the œsophagus cannot be seen, and, in fact, can scarcely be said to exist.

Structure.—The œsophagus is composed of a muscular and a mucous coat, with some connecting cellular tissue. The muscular coat of the œsophagus, which is considerably thicker than that of any other portion of the alimentary canal, consists of two distinct layers. The external layer is composed of fibres arranged in a longitudinal direction, and is twice the thickness of the internal layer, the fibres of which surround the canal in a circular manner. The longitudinal fibres are regularly disposed around the œsophagus; superiorly they arise in the median line from the posterior surface of the cricoid cartilage, and laterally on each side from the lower border of the inferior constrictor muscle of the pharynx; at the inferior extremity of the œsophagus they spread out and are continuous with the longitudinal fibres of the stomach. The circular fibres are a continuation of the posterior part of the inferior constrictor muscle, but they are much more delicate than the fibres of this muscle. These fibres pass for the most part transversely; the spiral arrangement which some anatomists have described does not generally exist in the human subject. The colour of the muscular fibres is pale red, less pale than those of the succeeding portions of the alimentary canal, and less deeply coloured than those of the pharynx. A microscopic examination shews them to be composed of both striped and unstriped fibres, mingled to an uncertain extent. "In some specimens from the human subject we have failed in detecting any striped fibres in the lower half of the œsophagus, either in the circular or longitudinal layer; but in other examples we have found them to within an inch of the stomach."*

Mucous membrane.—The mucous membrane of the œsophagus is of a pale colour; it presents a number of longitudinal furrows, which are produced by a slight folding of the membrane during the partial contraction or ordinary tonicity of the circular muscular fibres: the apparent laxity of the mucous membrane is no more than sufficient to allow of the dilatation of the canal which occurs during the process of deglutition. In addition to the longitudinal furrows there are some finer lines or wrinklings passing in various and indefinite directions, which are analogous to the fine grooved lines observed in the skin of various parts of the body. The mucous membrane is remarkable for its thickness; the epithelium is so abundant as to be distinctly visible to the naked eye; it forms a thick layer similar to a cuticle, and terminates at the cardiac orifice of the stomach in a well-defined irregular fringed border. It is composed of the lamelliform or scaly variety of epithelium.† The mucous membrane is connected with the subjacent muscular layer by the intervention of an abundant lax areolar tissue, which allows of a movement of these membranes upon each other during the repeated variations to which the diameter of the œsophagus is subject in the process of deglutition.

Œsophageal glands.—In the submucous areolar tissue of the œsophagus are found a number of small glands. They may be felt through the mucous membrane, which they elevate here and there, as little circular or oval flattened granular bodies; they are most numerous at the lower extremity of the tube. Their structure is the same as that of the buccal and duodenal glands. From the duct, which opens on the free surface of the mucous membrane, a few ramifications proceed and become embedded in the submucous areolar tissue. The branches are short and sacculated, having the appearance of small vesicles collected on a common stalk. The epithelium lining these glands is of the spheroidal variety.‡

Vessels and nerves.—The arteries distributed to the œsophagus are derived from several sources. In the neck they come from the inferior thyroid artery; in the chest some come directly from the aorta, others from the intercostals, and occasionally some from the internal mammary arteries; in the abdomen, branches are derived from the coronaria ventriculi and from the phrenic arteries. The veins corresponding to these arteries empty themselves into the inferior thyroid, the superior cava, the azygos, internal mammary, coronaria ventriculi, and phrenic veins. The *lymphatics* open into the glands which surround the œsophagus in considerable numbers. The *nerves* are derived chiefly from the pneumo-gastric. The recurrent branch of the pneumo-gastric in its course upwards sends numerous filaments to the œsophagus. In the chest, as the trunks of the pneumo-gastric nerves lie on the œsophagus, each one sends off filaments which pass backwards, encircling the tube, and meeting with branches from the opposite nerve. The plexus thus formed is called the plexus gulæ; it is joined by some filaments from the thoracic ganglia of the sympathetic.

Function.—The office of the œsophagus is to receive the aliment from the pharynx and to convey it into the stomach. This, the third and last stage of the process of deglutition, is unattended by sensation and uninfluenced by volition. The following is the mode in which the food is transmitted along the œsophagus. After being duly masticated and moistened in the mouth, it is received into the pharynx, and is thence propelled into the upper orifice of the œsophagus. The muscular fibres, both circular and longitudinal, of that part of the tube into which the food is propelled are at once stimulated to contract; the mass is consequently pushed onwards into the relaxed portion of the tube immediately succeeding; the stimulus of contact with this part produces the same effect upon it as has already been produced upon that part of the tube which the food has just quitted, and the contraction of the first portion continuing at the time when that of the second portion is taking place, the substance is necessarily propelled onwards: it thus comes into contact with successive portions of the tube, and in each successive portion the same effect is produced, the contact of the substance exciting contraction, and the remaining contraction of the part which it has just quitted preventing regurgitation. These phenomena occur in a much less space of time than is occupied in their description, and the food is rapidly transmitted along the entire length of the canal. A notion may be formed of the rapidity with which these contractions are transmitted along the œsophagus by observing the rapid vibrating movements in the neck of a horse while drinking. The secretion constantly poured out by the œsophageal glands has the effect of moistening and lubricating the interior of the tube, and thereby of facilitating the transmission of solid portions of food. The contractions of the œsophagus, which ordinarily commence at its pharyngeal and terminate at its cardiac extremity, sometimes take place in a reverse order, the direction of the movement depending on the part to which the stimulus is first applied. Dyspeptic persons are not uncommonly troubled with eructations of a liquid from the stomach, giving rise to what is fami-

* Physiological Anatomy and Physiology of Man, by Todd and Bowman.

† See the article Mucous Membrane.

‡ Ibid.

liarly called heartburn; and in pyrosis, or water-brash, the amount of liquid which suddenly enters the mouth is often very considerable. This inverted action of the œsophagus admits of a ready explanation. By the contraction of the muscular fibres of the stomach a portion of liquid is expelled into the lower extremity of the œsophagus; here it immediately excites contraction of the muscular fibres which surround it, and being prevented from again entering the stomach by the momentary continuance of the same effort which has expelled it into the œsophagus, it must necessarily pass into the relaxed portion of the tube immediately above; and thus, by the contraction of successive portions of the tube, the liquid soon reaches the pharynx. In ruminants, the greater portion of the food is returned from the stomach to the mouth by this inverted action of the œsophagus. During the action of vomiting there is an inverted action of the œsophagus in addition to the propulsive effort arising from the contraction of the stomach and abdominal muscles.

We have now to point out the precise mode in which these contractions are induced, to explain the intermediate links between the application of a stimulus to the mucous membrane and the occurrence of the muscular contraction. In the first place, unless we swallow a very large or a very hot morsel of food, no sensation attends its passage along the œsophagus. After the food has passed that portion of the pharynx upon which the glosso-pharyngeal nerve is distributed, we cease to be conscious of its presence; and again, when a bitter liquid is eructated from the stomach, it produces no sensation of taste until it reaches the same point. As the passage of food along the œsophagus is unattended by sensation, so is it uninfluenced by volition. We cannot by any effort of the will perform the action of deglutition unless we bring a portion of food, or a liquid (as the saliva), into contact with the pharynx, by means of which the action of the parts may be excited. Again, no effort of the will can arrest the process of deglutition after the food has entered the œsophagus, and if a liquid be made to pass into the pharynx of a person in whom the exercise of volition is suspended by a fit of apoplexy, deglutition is performed in a manner almost as perfect as by a person in health. An apparent exception to the general rule that the movements of the œsophagus are beyond the control of the will is afforded by the very rare examples of persons possessing the power of rumination. A voluntary power over the œsophagus, however, appears by no means necessary to account for this. It probably depends on the possession of an unusual degree of voluntary power over the movements of the stomach, and especially of its cardiac orifice, by means of which the contents of the stomach can be expelled at will into the inferior extremity of the œsophagus, and thus are brought within the influence of its involuntary movements. Any one may satisfy himself that he possesses some degree of voluntary power over the cardiac orifice of the stomach, if after swallowing a bottle of soda water he will direct attention to the power which he possesses of preventing the sudden escape of gas from the stomach, and, on the contrary, of increasing the propulsive effort probably by contracting the abdominal muscles. It is probable that many persons might by practice acquire the power of rumination. Since the contractions of the œsophagus cannot be excited by volition, are they dependent on the direct stimulus of the muscular fibres by contact of the food, independently of the nerves and of the nervous centres? That this is not the case is proved by an experiment performed by Dr. J. Reid.* He divided in a rabbit the vagus nerve on each side above the œsophageal plexus, but below the pharyngeal branches. The animal received the food which was offered to it, and by a propulsive effort of the tongue and pharynx transmitted it to the œsophagus, which, having lost all power of contraction, remained passive, and became at length completely distended and choked up by the materials thrust into it from above. It is evident then that the œsophagus loses its power of contraction if we cut off its communication with the nervous centres. As we have before seen that the will is not the agent which determines the contractions of the œsophagus, there remains but one explanation of these movements, which is, that they belong to the class of reflex actions. An impression made upon the mucous membrane of the œsophagus is communicated by the afferent nerves to the medulla oblongata, and thence an influence, the precise nature of which we are ignorant of, is reflected along the efferent nerves to the muscular fibres of the part to which the stimulus was applied. The only parts of this circle of actions which we recognise by our senses are the application of the stimulus and the occurrence of the muscular contraction; but these are doubtless connected in the manner above mentioned. The œsophagus receives both its excitor and its motor nerves from the pneumo-gastric; it thus derives its nervous influence from that portion of the nervous centre, namely, the medulla oblongata, which is the centre of the respiratory movements. Hence it will be seen that when in any case of disease of the nervous centres deglutition becomes seriously impaired, there is much reason to fear that the more important function of respiration will soon become involved.

Abnormal anatomy.—The œsophagus may deviate from the normal state in form or in structure. In some cases malformation may exist without obvious change of structure, but it is more common to find them combined. Malformation of the œsophagus may be either congenital or acquired.

Congenital malformation. — It sometimes happens that the œsophagus is congenitally deficient, terminating above in a cul-de-sac, the inferior extremity of the pharynx also terminating in the same manner. This is usually associated with an imperfect developement of the oral cavity and of the lower jaw, the latter

* See the Edin. Med. and Surg. Journal.

being in great part or altogether deficient. In some cases the pharynx does not terminate in a cul-de-sac, but opens by a small orifice at the side of the neck. Another congenital malformation more rare than the last consists in the division of a portion of the œsophagus into two canals placed side by side.

Acquired malformation.—One of the most common kinds of acquired malformation is dilatation either general or partial. In the Museum of King's College there is a remarkable specimen of a dilated œsophagus. At each extremity it is healthy and of the natural size; the intermediate part is enlarged to an extraordinary degree of dilatation; the lining membrane is thickened and opaque, and has the appearance of having partially yielded from dilatation. The muscular fibres were of the natural colour and thickness. The dysphagia in this case was as great as in a case of stricture.* Dilatation is a common consequence of stricture. In such cases the dilatation usually occupies the whole circumference of the canal. In some rare cases dilatation occurs in the form of a pouch projecting on one side of the canal. Occasionally the mucous membrane alone becomes pouched, protruding as a hernia between the muscular fibres, but more commonly the muscular coat also dilates and expands over the pouch. Bleuland mentions a case in which a large pouch containing alimentary matters compressed the canal below so as completely to close it, and to prevent the passage of food into the stomach. These pouches are most common at the upper extremity of the œsophagus, probably in consequence of the sudden constriction which the canal undergoes at this point, and partly too in consequence of the muscular coat being thinner here than in any other part.†

Structural changes.—Among the most common are those which result from inflammation, which however is seldom idiopathic, but generally the consequence of swallowing irritating substances, hot liquids, the strong acids or alkalies. The effects in such cases vary in degree from slight redness and softening of the mucous membrane, to ulceration and sloughing of the whole circumference of the tube. The Museum at King's College contains a preparation of an œsophagus and of a slough discharged from it, which was taken from a young woman who had swallowed oil of vitriol. A week afterwards she brought up a slough having a tubular form, and consisting of the whole lining membrane of the gullet. Some of the muscular fibres were plainly visible on the outside of the slough, in its recent state.‡ Dr. Baillie gives a drawing of a *false membrane* lining the pharynx and œsophagus, taken from a patient who had thrush.

The œsophagus is very frequently the seat of *stricture*, the causes of which are various. Not unfrequently it depends on the contraction of a cicatrix after sloughing produced by the contact of some irritating agent. The constriction in these cases appears to go on continually increasing. Sir C. Bell mentions a case in which starvation was the consequence of stricture of the œsophagus, *twenty years* after swallowing a quantity of soap lees. Another common cause of stricture is cancerous disease. This is generally confined to the lower extremity, but occasionally it pervades every part of the œsophagus.* A more rare case of stricture is described by Sir E. Home.† In this case a *membranous partition* extended across the canal; in the centre of the partition was a narrow passage; the coats of the œsophagus surrounding the stricture were but slightly changed. In cases of simple inflammatory stricture all the coats of the œsophagus are thickened and indurated at the seat of stricture, lymph is effused between them, and the bloodvessels are enlarged and distended. In consequence of stricture the œsophagus above becomes much dilated; sometimes ulceration and abscess occur. Dr. Monro mentions a case in which death occurred suddenly in consequence of purulent matter escaping into the trachea.

Morbid growths are occasionally found in the œsophagus. Dr. Monro‡ describes the dissection of a man aged 68, in whom the œsophagus was dilated by a large fleshy excrescence or polypus. It was attached three inches below the epiglottis and reached down to the upper orifice of the stomach. Haller§ gives an account of the dissection of a man, in whom was found a polypus about seven fingers' breadth long, and of the thickness of a worm, which in its general appearance it very much resembled; it had a carneo-fibrous appearance, a soft consistence, and a deep red colour. Fatty and steatomatous tumours have occasionally been found in the gullet. In other cases a portion of the canal has been found converted into bone, or cartilaginous tumours have grown from it.

An aneurism springing from the posterior part of the arch of the aorta may compress the œsophagus against the spine. The immediate consequence is difficulty of swallowing and other symptoms of stricture, and at length in many cases ulceration and sloughing of the œsophagus with escape of blood from the aneurism either into the mouth or the stomach.

OPTIC NERVES. Under this heading it is proposed to describe the special nerves of vision in *man*, for although other names are also employed by anatomists to denote the nerves in question, the above is preferred as being expressive of their functions. It should be borne in mind that the optic nerves are likewise frequently called "the second pair;" a term derived from their numerical position on the base of the brain, as they are the second from before backwards on the under surface of the encephalon.

The anatomy and physiology of the optic nerves *in man* constitute the more immediate subjects of the present article, but as these would be imperfectly treated without the aid of comparative anatomy, the reader will find in the following pages frequent references to the condition of the nerves of vision in other animals also.

Descriptive anatomy.

Apparent origin.—The optic nerves commence by two broad medullary tracts (the tractus optici), each of which becomes first apparent at the under surface of the corresponding optic thalamus.

Tractus opticus.—This appears to derive its principal origin from the corpus geniculatum externum: from that tubercle a narrow band arises which is soon reinforced by another (not in general equally large or distinct,) from the corpus geniculatum internum, and by the junction of the two the tractus opticus is formed: thus constituted, the tractus opticus takes a course forward and inward around the outer and inferior surface of the crus cerebri: it is at first deeply concealed from view in the great cerebral fissure, being overlapped from without by the middle lobe of the cerebrum, so as to be invisible until a portion of the brain, together with the arachnoid membrane and pia mater, have been displaced. Emerging from under cover of the middle lobe, the tractus next gains the front of the crus, runs along the margin of the tuber cinereum, and at length unites with the other tractus opticus to form the chiasma.

At the crus cerebri the tractus opticus increases in breadth, and of its two edges the anterior or external is here the thicker, while in the vicinity of the chiasma the tractus loses its flattened appearance, and becomes nearly cylindrical.

The tractus opticus is soft in texture *throughout*, being devoid of the tough neurilemma from which the *proper* optic nerve derives its uncommon firmness.

The tractus opticus receives a very extensive investment from the pia mater, which covers and adheres to all its free surface: *anteriorly*, where the tractus is approaching the chiasma, nearly two-thirds of its circumference are clothed by pia mater; and further back, that membrane even insinuates itself a short distance between the posterior or inner margin of the tractus, and the adjacent surface of the crus cerebri. The arachnoid has a far *less* extensive relation to the tractus opticus: in the early part of its course the tractus has no serous covering, but in the interval between the middle lobe of the brain and the chiasma, the arachnoid passes beneath the tractus opticus, and so affords it a partial investment.

The anterior or external margin of the tractus opticus is so closely connected to the crus cerebri that in attempts to separate them the medullary substance is torn, and consequently some anatomists are of opinion that the crus furnishes filaments of origin to the tractus; but the posterior or inner edge of the tractus is not identified with the crus, for there the two structures can be separated without any violence to either.

The third and fourth nerves, before reaching the cavernous sinus, cross underneath the tractus opticus, but not *immediately*, for the serous and vascular membranes of the brain, and in general the edge of the middle cerebral lobe are interposed; the posterior communicating artery passes also across the tractus inferiorly, and the artery of the choroid plexus, in its course to the great cerebral fissure, runs beneath it, the pia mater alone intervening between these bloodvessels and the tractus opticus.

The chiasma is somewhat quadrilateral, and receives by each posterior angle the corresponding tractus opticus, while its anterior angles are prolonged respectively into either optic nerve; when "in situ," it is supported by a transverse groove of the sphenoid bone in front of the sella Turcica. *Posteriorly*, it is identified with the tuber cinereum, and to its upper surface the peculiar greyish membrane which closes up the third ventricle is adherent. The chiasma has complex relations to bloodvessels; behind and below this body the anterior portion of the coronary sinus is situated; external to the chiasma the termination of the internal carotid artery is placed, and in front of it are the anterior communicating, and a part of the anterior arteries of the cerebrum.

Optic nerve proper.—This proceeds from the chiasma, and after passing through the foramen opticum into the orbit, and arriving at the eye-ball, it perforates the sclerotic and choroid coats, and terminates in the retina.

First stage.—In the short interval between the chiasma and the optic foramen, the optic nerve is directed forward and outward; its size is perceptibly greater than that of the tractus opticus: it is not perfectly cylindrical in shape, being slightly flattened above and below; it is covered immediately by a dense tough neurilemma, and provided besides with a distinct sheath of arachnoid membrane, which, after accompanying the nerve fairly into the hole in the sphenoid bone, becomes reflected on the process of dura mater lining that aperture. Shortly after its commencement the optic nerve is separated from the olfactory by the anterior artery of the cerebrum. The ophthalmic artery leaves the cranium by the foramen opticum also, and lies beneath the optic nerve and to its outer side, being there enveloped in a special sheath of fibrous membrane.

Second stage.—Having entered the orbit, the optic nerve inclines more directly forwards; in consequence of this change of direction it appears slightly bent at the optic foramen, the convexity of the curvature being turned outwards, and it traverses the fibrous and vascular coats of the eye at a point not exactly corresponding to the axis of the organ, but a little inferior and internal to that imaginary line.

Whilst in the orbit the optic nerve is completely cylindrical, but a circular constriction indents it just before piercing the sclerotic.

In this, its second stage, the optic nerve has still its neurilemmatous investment, and in addition, a perfect sheath of fibrous membrane, derived from and clearly traceable to the dura mater; this latter covering of the nerve possesses great strength and density; it is white and tough, and admits of ready separation from the proper neurilemma; moreover, it becomes continuous with the sclerotic, as the nerve is perforating that tunic.

In its course through the orbit the optic nerve is related to many of the important parts in that cavity; on leaving the foramen opticum it is surrounded by the posterior attachments of the muscles of the eye, and afterwards proceeds forwards to its destination through the centre of the space which has the recti for its limits. The nerve is here imbedded in a quantity of soft fat, from which it derives protection, and wherein other nerves and bloodvessels are immersed.

The nasal branch of the ophthalmic division of the fifth nerve (immediately after entering the orbit), the lenticular ganglion with its roots, and some of the ciliary nerves at their origin, the sixth nerve, and the ophthalmic vessels in their first stage, intervene between the *outer* surface of the optic nerve and the *external* rectus muscle.

Between the *upper* surface of the optic nerve and the *superior* rectus muscle, the superior division of the third nerve, the nasal branch of the ophthalmic division of the fifth nerve, and the ophthalmic artery and vein (in the second stage,) take their course; the vein being generally placed farther forwards than the artery.

Beneath the optic nerve, the inferior division of the third nerve is placed, and those twigs of the latter which are destined for the inferior and internal recti muscles separate the optic from the inferior rectus.

To the *inside* of the optic nerve and upon a higher plane, the ophthalmic vessels in their third stage, and the nasal branch of the ophthalmic division of the fifth nerve are situated; their position is rather above the upper edge of the internal rectus, but the branch of the third nerve which supplies that muscle separates it in part from the optic nerve.

The ciliary nerves run from behind forwards. Closely approximated to the optic nerve, they appear *mostly* above the nerve and on its lower and external aspects, but nevertheless one or two of the ciliary branches of the nasal nerve, as well as one or more from the lenticular ganglion, before piercing the sclerotic coat, gain, in general, the inner side of the optic nerve.

The long and short ciliary arteries in their course to the globe of the eye are intimately related to the optic nerve, some of the latter vessels appearing actually to twine around it in a spiral manner: and many of the muscular branches of the ophthalmic artery lie immersed in the surrounding adipose tissue, at no very great distance from the nerve in question.

Communication with other nerves.—The optic nerves have no direct communication with the other *cerebral* nerves, but certain anatomists have traced filaments from the *ganglionic* system to them. Arnold (Icones nervorum Capitis, Tabula Sexta) has described and delineated two slender threads which run from the spheno-palatine or Meckel's ganglion to the optic nerve, and Hirzel observed in several instances the same arrangement. Tiedemann has seen an excessively delicate filament from the lenticular ganglion accompanying the arteria centralis retinæ through the optic nerve: he has also discovered branches of the ciliary nerves taking the same course, and has even succeeded in following them as far as the retina; and M. Ribes (Mémoires de la Société Médicale d'Emulation) has asserted, that a minute subdivision of the cavernous plexus extends along the arteria centralis retinæ, being derived from that division of the plexus which accompanies the ophthalmic artery.

Organization.—The organization of the optic nerve is in many respects peculiar. *Firstly.* From the chiasma to its distal extremity it is enveloped by a strong coating of neurilemma, and from the inner surface of this tunic a number of processes are detached which divide the interior of the envelope into longitudinal canals wherein the medullary substance is lodged; the optic nerve is not therefore a mere bundle of nervous cords (the structure prevalent in other nerves), but it is "a cylinder of collected tubes." *Secondly.* From the optic foramen to the sclerotic a sheath of dura mater is superadded to the optic nerve, and since none of the other cerebral nerves possess a similar covering, it must be considered a special provision for the security of the second pair. *Thirdly.* The arteria centralis retinæ runs through the centre of the optic nerve (an anatomical arrangement of exceedingly rare occurrence): and the primitive fibres of the optic nerve evince a marked tendency to appear "varicose," a condition discovered by Ehrenberg, and considered by him and others peculiar to certain parts of the nervous system.

Real origin.—Anatomists have entertained very conflicting views upon this interesting question, so that from time to time different parts of the human encephalon have been considered the true origin of the optic nerves.

The older writers very generally believed that these nerves originate in the optic thalami, as the names "thalami nervorum opticorum" still applied to the bodies in question sufficiently attest, and Eustachius, Varolius, Lieutaud, Haller, &c. supported this opinion.

Others conceived that the nates (or anterior pair of the tubercula quadrigemina) are the principal source of the optic nerves; this was maintained by Ridley, Winslow, Zinn, Morgagni, Sanctorini, Girardi, Hildebrandt, Boyer, Bichat, and Sœmmerring; and the same views were still more powerfully advocated by Gall and Spurzheim, although *they* admitted that the nerves derive a reinforcement from the corpora geniculata externa and the tuber cinereum.

Tiedemann (although fully aware that *some* filaments of the optic nerves are traceable to the surface of the optic thalamus both in the fœtus and adult) yet believed the *nates* and *corpora geniculata* externa to be the true origins of the nerves under consideration, and in this opinion he was strengthened by the Report on the Memoir of Gall and Spurzheim, made to the Institute by Cuvier, Portal, Sabatier, and Pinel.

According to Serres the tubercula quadrigemina are the proper sources of the optic nerves, and by Leuret the second pair are traced to a triple cerebral attachment, viz. the nates, testes, and optic thalamus.

It is proposed to examine in this place some of the grounds on which the foregoing opinions have been founded, and to this inquiry the aid of comparative anatomy is indispensably requisite.

Fish.—In these animals the optic nerves are distinctly traceable to two of the ganglia which compose the diminutive brain. The ganglia in question are called "optic lobes," from being the principal sources of the nerves of vision; they are hollow, and their position in the brain is between the cerebral hemispheres and the cerebellum (*fig.* 407.) The optic lobes

Fig. 407.

in fish very generally bear proportion to the size of the optic nerves (a proof of their physiological relations); and this proportion becomes particularly apparent in fish which possess either unusually small organs of vision, as the Eel; or eyes of different dimensions, as the Pleuronectes.

Fig. 408.

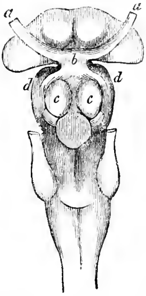
tubercles placed on the under surface of the encephalon beneath the optic lobes (*fig.* 410). The writer does not presume to decide whether these tubercles are really identical with the mammillary eminences of the human brain as maintained by Desmoulins and others; or with the tuber cinereum, as Carus, Spurzheim, &c. have contended: but that they have a share in the origin of the optic nerves is certain, since in those fish which have two optic nerves of *unequal* size, the tubercles to which allusion is made present corresponding differences in dimensions (*fig.* 409, *g g*).

Fig. 410.



Brain of a Ray. (From nature.) Seen from below.

a a, optic nerves; *b*, chiasma; *c c*, inferior lobes from which the optic nerves derive some of their roots; *dd*, optic lobes the principal sources of the optic nerves.

Reptiles. — In this class the optic nerves are derived from optic lobes very similar to those in fish; they are two in number and interposed between the cerebral hemispheres and the cerebellum: their size is proportional to the developement of the optic nerves, and they are best seen at the upper or dorsal surface of the brain (*fig.* 411, *c*).

Birds.—In birds the optic nerves originate chiefly in two lobes situated at the inferior and lateral aspect of the brain, and called in this class also "optic lobes." The size of these lobes is in proportion to that of the optic nerves and organs of vision, and they are therefore

Fig. 411.

what parts of the mammal's brain are analogous to the optic lobes of the lower classes.

The tubercula quadrigemina in man and the mammalia are identical with the optic lobes of the lower vertebrata; they occur as four small tubercles arranged in pairs, of which the anterior are called the nates, and the posterior the testes. In some of the class, as for example, Ruminantia, Solipeda, and Rodentia, the nates are of larger dimensions than the testes; in others, as for instance, Carnivora, the testes predominate in size over the nates, and in Man and Quadrumana the two pairs are nearly equal.

immense in birds of prey, and much smaller in other birds not equally remarkable for perfection of sight (*fig.* 412).

Fig. 412.

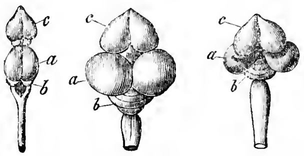
Fig. 413.



Brain of a chick. (After Serres.) At three different stages of incubation.

A, at sixth day; B, at tenth day; C, at fourteenth day.

A, *a, a*, optic lobes; *b*, rudimental cerebellum; *c, c*, cerebral hemispheres.

B, *a, a*, optic lobes separated from each other in front, and here slightly depressed; *b*, cerebellum inclining upwards and forwards between optic lobes; *c, c*, cerebral hemispheres growing backwards so as to overlap the optic lobes.

C, *a, a*, optic lobes still farther separated from each other and depressed towards base of brain; *b*, cerebellum growing upwards between the optic lobes; *c, c*, cerebral hemispheres carried backwards so as to come nearly into contact with the cerebellum. Reference to *fig*. 412 will shew the brain of the bird in its full-grown condition.

The situation of these bodies in the brain of the bird, so different from their position in reptiles and fish, created at one period some doubts as to their true analogies; but Serres has shown that during the early stages of developement the optic lobes occupy precisely the same position in the encephalon of the chick which they hold *permanently* in the brain of the reptile and fish, and he has thereby divested this subject of much of its obscurity. Thus before the tenth day of incubation the optic lobes of the chick are placed between the cerebellum and the cerebral hemispheres, and are then best seen at the *dorsal* aspect of the brain: but after this epoch the hemispheres and cerebellum approach each other at the expense of the optic lobes—the hemispheres extending backwards, and the cerebellum inclining forwards. By this double movement the optic lobes are soon overlapped behind, separated from each other, and at length pushed downwards and outwards to their permanent situation (*fig*. 413).

In Man the optic nerves derive some roots from the tubercula quadrigemina.

In birds, reptiles, and fish, the optic lobes constitute the principal sources of the optic nerves, and therefore in any attempt to ascertain the true origin of the second pair in *man*, a necessary preliminary will be to determine

The tubercles in question have but little *apparent* similarity to the optic lobes of the lower Vertebrata: *they* occur as *four* eminences, while the optic lobes of birds, reptiles, and fish, are but *two* in number: *they* are of diminutive size; the optic lobes of birds, reptiles, and fish are of *large* dimensions in proportion to the brain: *they* are *solid*; the optic lobes of birds, reptiles, and fish are *hollow:* and in Man and most Mammalia *they* are covered upon the upper surface by the cerebral hemispheres, while the optic lobes in reptiles and fish are not so covered. Such obvious dissimilarity tended materially to obscure the real nature of the tubercula quadrigemina, but a careful study of the developement of these bodies in the fœtal brain led anatomists at length to discover their true analogies; and the researches of Tiedemann and Serres have chiefly contributed to establish the following particulars.

" In the earlier stages of uterine life the tubercula quadrigemina of Man and Mammalia occur in the form of *two* masses; they persist as such during two-thirds of fœtal existence; they are hollow at first and *not* covered by the cerebral hemispheres, and their size is immense in proportion to the bulk of the encephalon. As developement advances, a transverse groove appears on the surface of the future tubercula quadrigemina; this divides them into *four* eminences, which are now for the first time really entitled to be called "quadrigemina:" nervous matter is gradually deposited from within on their walls, in consequence of which they henceforth become solid; their growth in size is arrested, and the cerebral hemispheres having grown backwards, overlap and conceal them from view. This overlapping occurs in all except a few of the lowest families of the mammalia, in which the tubercula quadrigemina remain permanently uncovered.

From the foregoing exposition it appears that during their developement the tubercula quadrigemina in man and mammalia assume *for a time* all the characters which the optic lobes of birds, reptiles, and fish exhibit in the *permanent* condition; and hence it can scarcely be questioned that the nates and testes of the former class are identical with the optic lobes of the latter animals; but since the optic nerves in the oviparous Vertebrata are traceable to the optic lobes and manifestly derive from them the greater proportion of their roots, there is so far primâ facie evidence that the optic nerves in *man* have their origin in part from the tubercula quadrigemina. In further confirmation of the same view it may be remarked that some of the roots of the optic nerves in certain orders of the mammalia are seen to spring from these bodies; for example, in the horse a large proportion of the nerves can be traced distinctly to the nates. In Rodentia and Carnivora numbers of the fibres of the nerves emanate obviously from the same pair of tubercles, and in the Ruminants a similar anatomical arrangement prevails.

As an additional proof Tiedemann asserts that although much difficulty is encountered in attempts to follow the optic nerves to the tubercula quadrigemina in the *adult* human subject, he has succeeded in tracing them to the nates in fœtuses of the third month, and at the fourth and fifth months he has frequently repeated the same observation.

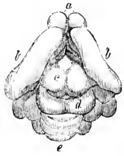
Human pathology would seem to furnish some corroborative facts: thus in every case of long-continued atrophy of the optic nerve, where the wasting had involved the tractus opticus, Gall and Spurzheim found the nates of the side corresponding to the diseased tract diminished in size; and the experiments instituted upon living animals with a view to determine the functions of the several constituents of the brain by the successive removal of the different parts of the organ and careful observation of the disturbance thereby produced, lead also to the belief that the optic nerves have an origin in the tubercula quadragemina. Of course great allowance must be made for inaccuracy in the result of such mutilations, but Flourens, Magendie, Desmoulins, and Hertwig, all agree that destruction or mutilation of the nates and testis of one side invariably produces blindness of the opposite eye.

The writer agrees fully with Cruveilhier in the belief that the optic nerves in the human subject can be rarely traced to the tubercula quadrigemina satisfactorily; but nevertheless with the above facts before them, anatomists can scarcely refuse to allow that the optic nerves in man derive a share of their roots from these eminences.

The tubercula quadrigemina probably fulfil other purposes besides that of affording origin to the optic nerves.

This may be inferred from the fact that the optic nerves are not invariably developed in direct proportion to the tubercles; thus in certain mammals which are either devoid of optic nerves altogether, or in which they are so excessively diminutive as to be with difficulty discovered, the tubercula quadrigemina are as large and perfect as in other allied species possessed of well-marked organs of vision.

Fig. 414.



Brain of a mole. (From nature.) Seen from above. The upper part of each cerebral hemisphere has been removed by a horizontal section.

a, a, olfactory lobes; *b, b,* cut surface of cerebral hemispheres; *c, c,* nates; *d, d,* testes; *e*, cerebellum. The nates and testes, or tubercula quadrigemina, are of immense size; the cerebral hemispheres are small.

The common mole, for example, has eyes so diminutive and imperfect in structure, and its subterranean habits bespeak so little necessity for organs of vision, that many excellent anatomists believe it to have no optic nerves; nevertheless the tubercula quadrigemina in this animal are of immense size. (*Fig.* 414) Serres never could satisfy himself that the mole possesses optic nerves, although he examined thirty or forty specimens for the express purpose, and if they do exist (as has been maintained by Carus and Treviranus) their minuteness must be almost microscopic. (See INSECTIVORA, vol. ii. *fig.* 453.)

Other examples confirmatory of the same views are afforded by the mammalia; it is stated on the authority of Serres that in the rat-mole of the Cape, and the Zanni, or blind rat-mole, there is no appearance whatever of proper optic nerves, (the rudimental eyes being supplied by the fifth pair,) and yet in these animals the tubercula quadrigemina exist in great perfection.

The human optic nerve probably derives roots from the optic thalamus.

The writer is of opinion that modern anatomists have fallen into error in supposing that *none* of the roots of the second pair are derived from the optic thalamus, although the arguments by which that supposition has been sustained are sufficiently imposing, viz.:—

"The size of the optic thalami is not in general in direct proportion either to that of the optic nerves or the acuteness of vision in animals.

"In most fishes the optic nerves are of great size, and the perfection of vision is extreme, yet in this class the optic thalami are absent.

"In birds, some of which enjoy exquisite powers of sight, the optic thalami are small.

"In mammalia the optic nerves bear no fixed proportion to the optic thalami; for instance, the horse, the ox, and the stag have larger optic nerves than the human subject, and yet the optic thalami in these animals are infinitely smaller than in man."

The foregoing arguments are not conclusive, for if the want of *direct* proportion between the optic thalami and optic nerves were a proof that the optic nerves draw *none* of their roots from the optic thalami, the very same principle would deprive the tubercula quadrigemina likewise of all claim to be considered a source of the second pair; since in the Mole and some other mammalia, already specified, the nerves in question and the tubercula quadrigemina actually occur in *inverse* proportion to each other.

In considering this question it should be recollected that in the mammalia *large* optic thalami are always found associated with *small* tubercula quadrigemina, and vice versâ; and the same remark applies to the optic thalami and optic lobes of the other vertebrata; thus in birds, the optic thalami are small, but the optic lobes are of large dimensions: in reptiles the same proportions are apparent: in fish the optic thalami disappear, but the optic lobes are immense, and two inferior lobes (an additional source of the optic nerves) are superadded. These facts favour the presumption that the optic nerves derive roots from the optic thalami; for if (as is most probable) the optic thalami and the tubercula quadrigemina *both* afford origin to the optic nerves, they may be mutually supplemental to each other; and in that case the *reciprocal* proportions of these eminences will be a matter of no consequence, provided only that their *sum* be proportional to the nerves.

In farther support of the opinion here advocated, it should be borne in mind, that the tractus opticus is clearly traceable to the surface of the optic thalamus in the human *adult* subject, and the writer's experience has convinced him that the same anatomical disposition is very apparent in early fœtal life (*fig.* 415). It may be well to add that in all the orders of the mammalia which he has had an opportunity of examining, the tractus opticus derives filaments from the optic thalamus: in the *horse*, although a large proportion of the tractus can be traced to the nates, its anterior fibres spring most distinctly from the optic thalamus (*fig.* 416);

Fig. 415.

in the *sheep* precisely the same arrangement exists: in the *hare* many filaments of the tractus opticus originate in the optic thalamus: and in carnivora and quadrumana a similar disposition prevails.

Recent microscopic discoveries in ovology (if it be fair to argue from the developement of the chick to the evolution of the human fœtus) tend to confirm the views here put forward. Baer states that on the fourth day of incubation the encephalon of the chick consists of several cells, one of which corresponds to the third ventricle, and another to the optic lobes, and *that these two cells are distinct from each other.* The first rudiment of the eye observable in the chick occurs in the form of a vesicle which shoots out from the parietes *of the cell of the third ventricle*, and which becomes gradually elongated and drawn out into a canal. On the fourth day the eye represents a spherical cavity communicating with the third ventricle by a canal; this canal is the rudimental optic nerve, which becomes gradually solid, its cavity disappearing after the sixth day. During the earlier periods of growth there is no connection whatever between the optic nerves and the cell of the optic lobes, but the nerves just specified are from the very commencement in free communication with the cell of the third ventricle, *and in the walls of that cell the optic thalami are developed.*

The evidence which pathology has afforded upon this question must be considered unsatisfactory in the extreme; for, on the one hand, well authenticated cases are recorded in which vision remained perfect although the optic thalamus was extensively diseased, and Gall and Spurzheim have observed atrophy of the optic nerves to reach the nates without affecting the optic thalamus: while, on the other, Cruveilhier has seen the corpus geniculatum externum involved in the wasting of the optic nerve, and Magendie and Desmoulins, from their own researches and experiments as well as from those of Nœthig and Sœmmerring, infer that after long-continued blindness the atrophy of the optic nerve in man sometimes affects the optic thalamus.

The following is a summary of facts favourable to the supposition that the optic nerves in man derive roots from the optic thalami.

1. The human tractus opticus admits of being distinctly traced to the optic thalamus, both in the fœtal condition and subsequently to birth.

2. In many, if not all, of the mammalia, the optic nerves in the clearest manner derive roots from the optic thalami.

3. The optic nerve of the chick first appears as an offset from the third ventricle, and the optic thalami are developed in the walls of that ventricle.

4. The inverse proportion known to subsist between the tubercula quadrigemina and the optic thalami in mammalia, and also between the optic lobes and the optic thalami in birds, reptiles, and fish, may probably be considered corroborative facts.

Corpora geniculata: their relation to the optic nerves.

That there is an intimate physiological relation between the optic nerves and the corpora geniculata can scarcely admit of doubt, for the principal band of the human tractus opticus is, in *every* instance, traceable to the corpus geniculatum externum, and may be seen actually incorporated with that tubercle; and a similar connection between the lesser band of the tractus and the corpus geniculatum internum is also, for the most part, discoverable: moreover, in various orders of the mammalia a portion of the tractus opticus emanates most distinctly from the corpus geniculatum internum; and in quadrumana, carnivora, rodentia, &c., this has been frequently verified by the writer.

From the statements of Tiedemann, it appears that the corpus geniculatum externum is much more tardy of developement in the fœtus than the optic nerve itself, for the eminence in question becomes only for the first time apparent about the sixth month of fœtal life: again Serres affirms that both corpora geniculata appear so late as the sixth month of uterine existence; and according to the joint testimony of these two authorities, the corpora geniculata are developed in the *course* of the tractus opticus, and superadded to the rudimental optic nerve.

The late appearance of the corpora geniculata in the embryo, and the manner of their developement, would seem to assimilate these tubercles to the ganglions found in the course of certain nerves of special sense in many animals, and which are perhaps destined to exalt the sensibility of the nerves in which they occur. The optic ganglions of the loligo (*fig.* 424, *c*), and the olfactory ganglions of many fishes, afford good examples of the nervous masses to which allusion is here made.

Tuber cinereum: its relation to the optic nerves.

The same difficulties uniformly encountered in all attempts to determine the particular functions of individual parts of the brain prevail in the case of the tuber cinereum: some physiologists maintained that the optic nerves derive a great number of filaments from that body, and that the nerves are considerably increased in dimensions by this addition: Gall, for instance, was of this opinion, and gave a rather exaggerated representation of the enlargement supposed to arise out of this reinforcement to the nerves.

The optic nerves in man *may* doubtless draw some of their roots from the tuber cinereum, but there is an absolute certainty that the body in question has other and probably more important functions than any connected with the origin of the nerves of vision. Pathological and experimental observations upon the subject are still a desideratum, but in the absence of more direct evidence the anatomy of the mole's brain is calculated to throw some light upon the enquiry. In the mole the optic nerve is either wholly absent, or if present, it is merely rudimental; nevertheless, the tuber cinereum is of enormous dimensions; it extends forwards to the olfactory lobes, and so far backwards as nearly to reach the pons. In this animal, therefore, there is an *inverse* proportion apparent between the optic nerve and tuber cinereum, a fact little favourable to the hypothesis advocated by Gall.

Of the chiasma of the optic nerves.—The word chiasma (from the Greek χιασμος, *decussatio,*) means in strictness a decussation, or crossing at acute angles, like the legs of the letter X;* and, for convenience-sake, the same expression (with a like latitude of application) will be here employed to designate the corresponding structure in the lower animals.

The organization of the human chiasma has abundantly exercised the ingenuity of anatomists, who seem to have encountered great difficulty in their attempts to trace the nervous filaments through it; and consequently, notwithstanding all the attention bestowed upon the subject, opinions the most conflicting have prevailed upon the true nature of the structure in question. In no other instance is a similar junction between two corresponding nerves of opposite sides known to occur. Such an anomaly affords strong presumptive evidence of the existence of some unusual properties in the

* In Human Anatomy the term is used (without perhaps sufficient regard to its etymology) to express the nervous mass in which the two optic nerves are conjoined.

nerves thus united; and for these reasons the physiology of the chiasma is invested with uncommon interest.

The existence of a chiasma is not *general* throughout the animal series, and even when present it exhibits much diversity of appearance and structure in different classes. A brief exposition of some of its more striking varieties, *in animals*, will probably constitute the best introduction to the study of the chiasma in *man*.

Invertebrata.—In the invertebrate classes nothing like a chiasma has been demonstrated, nor has any mutual crossing of the special optic nerves been proved to exist. The nerves which are furnished to the compound eyes of insects and crustaceans pass in a *direct* course to their destination; the same remark applies to the nerves from which the lens-eyes of insecta, arachnida, crustacea, and mollusca, derive their sensibility; and it may be presumed that the nerves which supply the simple eye-dots of annelida and other inferior animals are similarly circumstanced.

Osseous fish.—In osseous fish the optic nerves generally cross each other at an acute angle, in such manner that the nerve which comes from the *right* side of the brain goes distinctly to the *left eye*, and vice versâ: at the point of decussation the nerves lie one over the other; they are usually flattened at this spot, and closely joined together, but this junction is effected by means of cellular or fibrous adhesions only, as no intermingling of the nervous filaments takes place, and the nerves themselves can be isolated without injury to their proper structure (*fig.* 407).

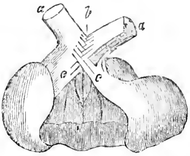
Cartilaginous fish.—In cartilaginous fish a well-marked chiasma occurs. In this class the junction of the two optic nerves is no longer effected by means of mere cellular adhesions, as in the osseous fish, but a perfect union of the proper substance of the nerves constitutes a true chiasma. The optic nerves arise each from the corresponding optic lobe chiefly; they quickly converge, and soon become confounded with each other in the chiasma; and so intimate is their connection, that anatomists possess little information as to the exact arrangement of the nervous filaments in this structure (*fig.* 410).

Birds.—In birds the chiasma is large, being proportional to the size of the optic nerves; by a little management its organization can be accurately demonstrated. Maceration for a few days in spirits hardens this structure sufficiently to enable the operator to strip off the neurilemma, and then, even without the aid of a lens, the chiasma may be seen to consist chiefly of laminæ. Forcible extension of the optic nerves, in such a manner as to tear through the superficial stratum of the chiasma on its lateral aspect, greatly facilitates the examination.

The laminæ originate in the tractus opticus, and appear to spring from the inner part alone of that mass; they gain the chiasma, and here those derived from opposite sides of the brain form a reciprocal interlacement. A perfect and regular decussation of the inner filaments of the two tractus optici thus takes place in the chiasma, in such manner that a large proportion of the tractus of one side is evidently traceable to the opposite optic nerve, and vice versâ: but the outer part of each tractus opticus continues on to form the outer part of the optic nerve of its *own* side, and has no concern in the formation of the decussating laminæ.

The number of laminæ in the chiasma of different birds is subject to some variety, but in the entire class, without exception, the laminated structure prevails (*fig.* 417).

Fig. 417.



Chiasma of the common fowl. (After Müller.)

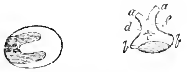
a, a, optic nerves; *b,* chiasma, dissected so as to shew its decussating laminæ; *c, c,* tractus optici.

Amphibia and reptiles.—In amphibia and reptiles a laminated chiasma, somewhat similar to that just described in birds, occurs; but the decussating laminæ are very variable in number, and in general much fewer than in birds.

Thus, in Amphisbœna, according to Müller, there are only five laminæ in all, two from one side, and three from the other; and in lacerta ocellata, according to the same authority, as many as eight have been counted, four on either side (*fig.* 418). In some reptiles the posterior part of the chiasma is strictly commissural, the inner part of each tractus opticus being appropriated to the formation of a band-like commissure: in Amphisbœna a triangular space separates this band from the remainder of the chiasma (*fig.* 418).

Fig. 418.

A. B.



Chiasma in Amphisbæna. (After Müller.)

A, section of chiasma to exhibit the decussating laminæ, of which there are three from one side and two from the other.

B, chiasma seen from below.

a, a, optic nerves; *b, b,* tractus optici; *c,* commissural band; *d,* triangular space; *f,* true chiasma.

Mammalia and man.—In mammalia and man the chiasma is no longer laminated, and great difficulty occurs in attempts to display its real structure.

The older anatomists were evidently unable to trace the filaments of the human optic nerves satisfactorily through the chiasma, and in consequence they relied either on pathological facts, or the results of experiments, or the data furnished by comparative anatomy, to determine the mutual relations of the second pair in this part of their course. The conclusions arrived at by such modes of investigation were unsatisfactory, and remarkable for much discrepancy.

1. Some maintained that the nerves are merely placed in exceedingly close juxtaposition in the chiasma, without any intercrossing of their respective filaments, and that each tractus opticus in reality passes on to form the optic nerve of *its own side*.

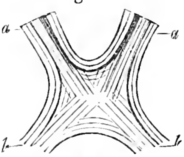
These views were supported by Vesalius,* who detailed the particulars of a case in which after death the two optic nerves were found perfectly distinct from each other throughout their whole course, and consequently no chiasma existed, although, during life, vision had been unimpaired; and the same hypothesis was strengthened by Santorini and others, who, in certain instances where one eye had been destroyed many years before death, observed on the post mortem examination the *corresponding* optic nerve atrophied as far back as the chiasma, and the tractus opticus of *the same side* wasted, while the nerve and tractus of the opposite side were perfectly healthy.

2. Others were persuaded that a perfect decussation exists in the chiasma, and that all the filaments of the tractus opticus of *one* side pass fairly across to form the optic nerve of the *other*, and vice versâ. In favour of this opinion it was urged that in the majority of cases of long-continued blindness of a single eye the *opposite* tractus opticus, and not the tractus on the *same* side with the affected eye, becomes atrophied. Sœmmerring observed several such cases in the human subject, and traced the same appearances in the horse, dog, squirrel, rabbit, hog, cat, and chamois: and Cuvier preserved in spirits the brain of a horse in which the wasting of *one* optic nerve continued backwards into the *opposite* tractus. The evident manner in which the optic nerves in osseous fish cross each other (see *fig.* 407) was also considered favourable to this view, and the results of experiments on living animals were confidently appealed to in farther confirmation of the same. Thus the experiments of Rolando, Pourfour Petit, Saucerotte, Hertwig, Flourens, and others led to the conclusion, that if in the Mammalia one hemisphere of the cerebrum be injured deeply or removed, vision becomes impaired or destroyed in the *opposite* eye; if the *two* cerebral hemispheres be successively subjected to the same treatment, vision becomes successively impaired or destroyed in *both* eyes; if *one* of the nates be removed, the animal sees no longer on the *opposite* side; and if *both* be removed, blindness affects *both* eyes in succession and occurs constantly in the eye *opposite* to the injured tubercle; if in birds *one* of the cerebral hemispheres be removed, vision becomes extinguished in the *opposite* eye; if the *two* hemispheres be removed in succession, a cross paralysis affects the *two* retinæ: if *one* of the optic tubercles be removed, the sight of the *opposite* eye fails, and if *both* be removed, *perfect* blindness ensues.

3. Another class of physiologists believed that a partial decussation occurs in the human chiasma, and that some of the filaments of each tractus opticus continue on into the nerve of their own side, while others cross obliquely into the optic nerve of the opposite side. Certain facts in pathology seemed difficult of explanation on any other supposition; thus cases of long-continued blindness of *a single eye*, the result of accident, have been met with, in which after death the *corresponding* optic nerve was found atrophied as far back as the chiasma (the optic nerve belonging to the healthy eye being of fully its ordinary dimensions, or even larger than natural) while *both tractus optici* were wasted.

That a partial decussation *does* occur in the human chiasma can now no longer admit of doubt, for of late years the existence of this organization has been proved by actual dissection, and it can be rendered apparent to the naked eye by the precaution of hardening the nervous substance before the dissection is commenced. According to the writer's experience immersion in spirit hardens the preparation in the most satisfactory manner. In performing the dissection the neurilemma must be first carefully removed from the chiasma, and also from the adjoining portions of the optic nerves and tractus optici; after this preliminary, each optic nerve should be divided transversely a little in front of the chiasma; a transverse incision carried horizontally into the cut surface of the cerebral extremity of each nerve will then enable the operator to split it in a direction backwards towards the chiasma, and by proceeding cautiously a horizontal division of the chiasma, and of a part of the optic nerves and the tractus optici, will be effected. (*Fig.* 419)

Fig. 419.



Human Chiasma. (From a dissection made by the writer.)

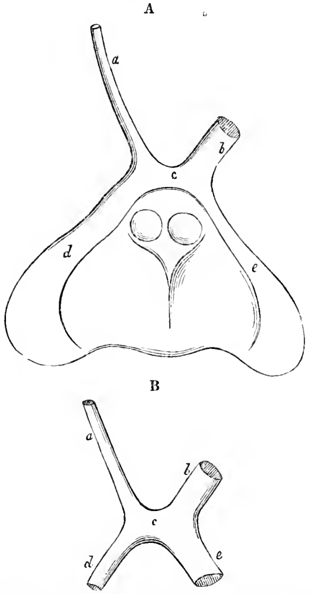
a a, optic nerves; *b b*, tractus optici.

The annexed figure represents a preparation made in the manner described, and it is essentially similar to a diagram of the human chiasma published some years since by Mayo; the primitive filaments of the nerves are of course invisible, but the direction of the larger fasciculi admits of not the slightest question; the outer fasciculi of each tractus opticus continue onwards without interruption to form the outer part of the optic nerve of the *same* side: the middle fasciculi cross the chiasma obliquely, and after decussating the corresponding fasciculi of the other tractus, contribute to the formation of the optic nerve of the *opposite* side; and the internal fasciculi cross the posterior part of the chiasma transversely and uniting directly with the corresponding fasciculi of the other tractus seem to be strictly commissural; across the front of the chiasma some fasciculi take an arched course, and being prolonged forwards along the inner edges of the optic nerves they are likewise apparently commissural.

* Vesalius de Corp. Hum. Fab., l. iv. c. iv.

Some difficulty no doubt arises when the physiologist attempts to reconcile with this anatomical arrangement certain facts already detailed: it may be remarked, however, that arguments derived from the pathology of the optic nerve can be but of little value, since they have been relied on in turn by the framers of each hypothesis as affording proof of their own peculiar views; and in the Museum of the Richmond Surgical Hospital, Dublin, the writer has seen specimens of atrophied optic nerves in man which furnish the most contradictory evidence upon the subject under discussion. The preparations alluded to were cases in which *one* eye had been destroyed either by local disease or accident, many years previous to death, and where in consequence the *corresponding* optic nerve became wasted from disuse, while *the other* optic nerve continued healthy. In the majority of these specimens the wasting has been propagated backwards to the *opposite* tractus opticus and has implicated that structure, while the *corresponding* tractus has been spared (see *fig.* 420, A); in some examples *both* tractus optici have suffered a diminution of size and in general to an unequal amount; and in one very remarkable instance the tractus opticus of the *same* side with the shrunken nerve has dwindled into a narrow band, while the *other* retains fully its normal dimensions (*fig.* 420, B).

Fig. 420.



Atrophy of one optic nerve, the consequence of long-continued disuse. (From preparations in the Museum of the Richmond Hospital, Dublin.)

A. *a*, right optic nerve in a state of atrophy; *b*, left optic nerve healthy; *c*, chiasma; *d*, right tractus opticus healthy; *e*, left tractus opticus wasted.

B. *a*, right optic nerve atrophied; *b*, left optic nerve healthy; *c*, chiasma; *d*, right tractus opticus wasted; *e*, left tractus opticus healthy.

It may be fair to add, that the case quoted from Vesalius is considered by many, and amongst others by Gall and Spurzheim, as of doubtful authenticity, and the results of experiments on living animals should be received with caution, for to argue from experiments on birds to the human subject is plainly fallacious, since the structure of the chiasma is not identical in the two cases, and the great obstacles encountered in the performance of such experiments on the *mammalia* renders them of trifling value.

Use of the chiasma.—In the direct junction between two corresponding nerves of opposite sides displayed in the chiasma, the second pair form an exception to a general law; for in no other known instance does a similar union occur; it therefore becomes a subject of great interest to determine how far this anomaly admits of explanation by any unusual properties in the nerves so circumstanced.

The optic nerves possess the remarkable power of conveying to the individual the sensation of a *single* impression *only*, while a separate impression affects each nerve simultaneously, so that although a perfect picture of the object be depicted on each retina severally, nevertheless to the spectator it appears to be single (as is really the case); or to speak still more intelligibly, a spectator sees an object *single*, although he looks at it with *two* eyes.

This property would seem to belong in an especial manner to the optic nerves, and inasmuch as the second pair differ from all the others in possessing a chiasma, there is so far a presumption, that the unity of sensation manifested by the optic nerves depends on the chiasma.

The idea that single vision may be explained by a partial decussation in the chiasma originated (upon theoretical grounds) with Newton; it has since been adopted by Wollaston, Solly, and others, and many facts have been from time to time brought forward in its favour. The hypothesis may be thus enunciated. " Each tractus opticus sends some filaments across the chiasma to form the inner part of the *opposite* optic nerve, while its outer filaments continue on to form the outer part of the optic nerve of its own side; the same arrangement of the filaments prevails to the retina, so that the right side of each retina comes from the right tractus opticus, and the left side of each retina from the left tractus opticus; if then in vision the pictures of an object be depicted simultaneously either on the right sides of the two retinæ, or on the left sides of the two retinæ, the impressions in either case will be communicated to one and the same tractus opticus; such impressions will of course be referred to one and the same side of the brain, and they will *therefore* produce the sensation of a single impression *only*, although in reality two several impressions affect the retinæ; the unity of sensation depending on the fact that the two impressions are referred to *the same side* of the brain, and not to opposite sides of the brain as occurs in other cases."

Wollaston adopted this hypothesis in consequence of the ready explanation it affords of certain cases of *visus dimidiatus:* he on several occasions in his own person experienced a temporary defect of vision, in consequence of which one and the same lateral half of every object became invisible, whilst he still continued to see the other half distinctly; and the same amount of blindness subsisted whether he employed one or both eyes in looking at the object.

Examples of the same form of amaurosis are of no very unfrequent occurrence, and according to the theoretical notions just propounded this partial loss of vision originates in some functional affection of *one* tractus opticus whilst the other remains healthy; those parts of the two retinæ which derive their origin from the *faulty* tractus being supposed to labour under a temporary amaurosis, while all other parts retain their ordinary sensibility.

In further support of this hypothesis, Muller's researches have convinced him that in man single vision by the two eyes occurs only when *certain* parts of the two retinæ are affected simultaneously, and that under other circumstances double vision ensues. This conclusion has been arrived at, chiefly from the results of experiments upon the eye-ball. Thus, when the eye-lids are closed in a dark room, if pressure be applied deeply to the eye so as to affect the retina, luminous spectra are produced. When *certain parts* of the two eye-balls are subjected to pressure at the same time, a single spectrum occurs, and when *other parts* of the two eye-balls are pressed upon simultaneously two spectra appear. Those parts of the two retinæ which in the above experiment furnish a single spectrum are styled " identical," in consequence of their identity of sensation; and those parts which produce two spectra are denominated " non-identical," for obvious reasons. Some of the conditions under which single and double vision respectively take place, seem to be confirmatory of this doctrine of " identical " and " non-identical " parts in the two retinæ; thus double vision is a common consequence of any cause having a tendency to disturb the relative directions of the optic axes: for example, diplopia frequently occurs in cases of strabismus, and double vision may (according to Muller) be produced in perfectly healthy eyes by a simple experiment: if a spectator fix his eyes upon an object and then press on one of them in such manner as to alter the direction of its axis, the object which at first seemed single will assume a double appearance. These phenomena admit of explanation on the supposition that in consequence of the distortion of the axes of the eyes, the visual impressions take effect on " non-identical " parts of the two retinæ, which *therefore* propagate *two* impressions instead of one to the sensorium.

These views apparently strengthen Newton's hypothesis, for it may be presumed that the " identical " parts of the two retinæ are those which derive their origin from *the same* tractus opticus, and the " non-identical " on the contrary those which come from different tractus optici.

The comparative anatomy of the nerves in question furnishes some facts favourable to Newton's hypothesis; thus many animals in which the eyes are directed *laterally*, in such manner that each embraces a totally different field of vision, have no chiasma, and their optic nerves cross each other, so that the right retina is in connection solely with the left side of the brain, and vice versâ. This arrangement prevails in the majority of osseous fish, and, for so far, affords *negative* proof of the hypothesis under consideration. The following theoretical explanation may be offered. " In these animals, owing to the position of their eyes, the same object can never be depicted on the two retinæ simultaneously; consequently, in them no provision to ensure single vision of the same object by both eyes is required, and therefore no parts of the two retinæ have a common connection with one and the same side of the brain, the two optic nerves being derived respectively from *opposite* sides of the organ."

Again, Mr. Solly has shown that in many fish, such as the skate, (in which the eyes are so set that the respective fields of vision may comprise in a great measure the same objects,) a chiasma exists: and the anatomy of the chiasma in birds is likewise on the whole favourable to the hypothesis; for in these animals the optic axes are in general very divergent, and consequently the respective fields of vision can have but little identity; a fact which agrees theoretically with the almost perfect decussation observable in their laminated chiasma.

Although this explanation of single vision has been sanctioned by the authority of Newton and Wollaston, and supported by strong anatomical facts and analogies, it will scarcely stand the test of critical examination; its validity has therefore been much questioned and apparently with justice, for the following reasons:

1. " Identity of sensation " is not *exclusively* a special attribute of the second pair; although it exists in them in great perfection, *other* nerves must also be admitted to possess the same property; thus notwithstanding that both ears are commonly employed simultaneously for the ordinary purposes of hearing, the sensation of a *single impression* of sound is in general propagated to the sensorium; and although both nares are used in the appreciation of odours, the sensation of *single impressions* of scents is most usually produced: now since neither the olfactory nor the auditory nerves are provided with a chiasma, and nevertheless these nerves undeniably evince a unity of sensation, there is good reason for scepticism when the very same property in the optic nerves is attributed to the presence of a chiasma.

2. Many facts in pathology are obviously at variance with Newton's theory; if it were the true explanation of single vision, morbid affections of one side of the brain (whenever productive of amaurosis) ought to implicate more or less of one half of *each* retina, whereas expe-

rience proves that in the majority of such cases one or other retina is *wholly* paralysed, and not unfrequently vision continues *perfect* in one eye although extinguished in the other. Moreover, although the theory in question affords an *ingenious* explanation of the defect in vision noticed by Wollaston, such explanation can scarcely be the true one, for Mayo has known "this visus dimidiatus to alternate in the same individual with temporary insensibility of the centre and circumference of the retina," and, as he observes, "the three phenomena being alternative no doubt proceed from the same organic source, but as the hypothesis will not explain *two* of them, it is probably not the right explanation of the third."

3. The structure of the human chiasma does not afford satisfactory explanation of the so called "identical" and "non-identical" parts of the two retinæ as laid down by Müller, and this has been so clearly shown by himself that his own words are quoted :—

"With reference to their identity of sensation, the two retinæ must be considered as included one within the other, so that all points of the two retinæ which lie within the same degrees of latitude and longitude (the eyes being regarded as globes) are identical in their sensations; all other points in the two retinæ are opposed to each other or different, just as any two points in the retina of the same eye.

"If the image fall on identical points in both eyes it will be seen single, and if the image does not fall on such identical points it will appear double.

"The two globes of the eyes are most minutely divided into degrees, minutes, and seconds of latitude and longitude; at all corresponding points they are identical, at all different points *non-identical.* The *outer* lateral portion of one eye is identical with the *inner* portion of the other eye; the upper part of one retina is identical with the upper part of the other, and the lower parts of the two eyes are identical with each other.

"The left half of the retina A, from 1 to 5, however, (*fig.* 421,) is not, as a whole, identical with the left half of the retina B, from 1 to 5, but certain points only of the left halves of both retinæ are identical, viz. those which in the two

Fig. 421.

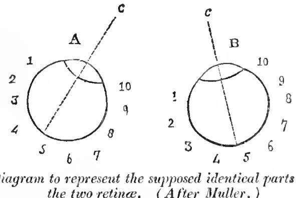


Diagram to represent the supposed identical parts of the two retinæ. (After Muller.)

1, 2, 3, &c., the identical parts of the two retinæ; *c, c,* the optic axes.

retinæ occupy the same degrees of latitude and longitude: 1 is identical with 1, 2 with 2, and so on; but 1 in the one eye is not identical with 5 in the other eye.

"To explain the single vision, therefore, it is necessary that not merely each root of the optic nerve, but each primitive fibre of each root should in the chiasma divide into two branches for the two optic nerves, so that the identical fibres of the two nerves might communicate with the brain at one point only, viz. by one radical fibre, as in the annexed woodcut (*fig.* 422). But such a division of the fibres in the chiasma does not exist: Treviranus and Volkmann were unable to detect any division of fibres in the chiasma, and I also was unsuccessful in my search for such dividing fibres. (*Fig.* 422.

a, a, optic nerves; *b, b,* tractus optici; *c, c,* supposed division of each radical fibre in the chiasma into two branches, one for each optic nerve.

4. If single vision in *man* be explained on the assumption that certain parts of the two retinæ are reciprocally identical, and that such identity depends upon a partial decussation in the chiasma, single vision in *animals* should of course admit of explanation upon the same principles; and if this be granted, the relative directions of the optic axes in the vertebrate classes ought to afford a good criterion of the extent to which the retinæ are reciprocally identical; for when the optic axes have a strictly lateral direction (as in many osseous fish), the same object can never be depicted on both retinæ simultaneously, and consequently it may be inferred that, in such cases, no parts of the two retinæ are reciprocally identical. Again, when the optic axes are very divergent, as in many quadrupeds, the respective fields of vision must comprise in great measure *different objects,* and under such circumstances it may be presumed that the two retinæ have but little identity. And when the eyes are so set that the optic axes are parallel, or capable of becoming parallel, or convergent (as in man), the same objects, or nearly the same, will almost constantly occupy the two fields of vision; and in such case the greatest amount of reciprocal identity may be assumed to occur in the two retinæ.

Now, if the relative directions of the optic axes in animals bear relation to the amount of reciprocal identity in their retinæ, and if this reciprocal identity depend upon the decussation in the chiasma, as has been assumed, the structure of the chiasma in animals generally should vary as the relative directions of their optic axes.

Such variation in the structure of the chiasma has not, however, been proved to occur generally throughout the animal series; on the contrary, the chiasma usually conforms to the type prevalent in the class to which the animal belongs, without evincing in its conformation much regard to the relative directions of the optic axes; and examples are not unfrequent in which the anatomy of the optic nerves is *at variance* with what the relative directions of the optic axes would require theoretically.

Thus in the pleuronectes fish, (*fig.* 409,) the optic axes are so directed that the two retinæ may be inferred to have a certain amount of identity, and nevertheless, in such of them as have been examined by the writer, the optic nerves are severally derived from *opposite* sides of the brain, and cross each other without forming a chiasma; or in other words, retinæ evincing mutual identity are supplied by optic nerves which have *no* identity of origin; the type prevalent in osseous fish being preserved, without respect to the directions of the optic axes. In many of the cetacea, the direction of the optic axes is such that the retinæ can have no identity, and nevertheless a perfect chiasma, such as occurs in other mammalia, exists in these animals. And in the owl the eyes look more directly forwards than those of most other birds, from which it may be presumed that the amount of mutual identity in the two retinæ is much greater in them than in those birds whose eyes have a lateral aspect; but nevertheless the structure of the chiasma in the owl appears in nothing different from that which prevails in birds whose optic axes have a strictly lateral direction.

But further, when the optic axes are very divergent, as in some quadrupeds, any object which can be depicted upon both retinæ simultaneously, will throw its images on the *outer* parts of the two retinæ, and in order to explain single vision under such circumstances, the outer parts of the two retinæ should therefore be reciprocally identical; but these parts are formed by the outer filaments of the optic nerves, which come respectively from the *corresponding* sides of the brain, so that here, reciprocally identical parts of the two retinæ, instead of having a common origin at one and the same side of the brain (as they ought in order to suit theoretical views), are derived severally from *opposite* sides of the organ, and consequently have no identity of origin (*fig.* 423). These considerations are sufficient to falsify the explanation of single vision put forward above, and the writer is of opinion that hitherto the exact use of the chiasma has not been discovered. (See Vision.)

Some remarkable varieties of optic nerves.

Optic nerves in certain cephalopods.—The loligo or calamary exhibits in its optic nerves a singularly beautiful arrangement, which the physiologist cannot but contemplate with the greatest interest, as it presents the most perfect decussation of nervous filaments hitherto discovered. The loligo, in common with some of the allied families of the cephalopoda, possesses an extremely perfect organ of vision; so elaborate is the mechanism of the eye that it has attracted a considerable share of attention from comparative anatomists; and the developement of the optic nerve bears proportion to the perfection of the other parts of the visual apparatus.

The nervous system of the loligo conforms to the cyclogangliate type, and from each lateral surface of the supracesophageal ganglion, (*fig.* 424,) one of the optic nerves comes off. After pursuing a short course outwards the nerve swells into a large ganglion (the optic); this body is oval in shape, and of enormous dimensions; it exceeds considerably the volume of the supracesophageal ganglion. One surface of the optic ganglion is directed towards the eye, and emits an immense number of filaments, which spring chiefly from its edges, and which,

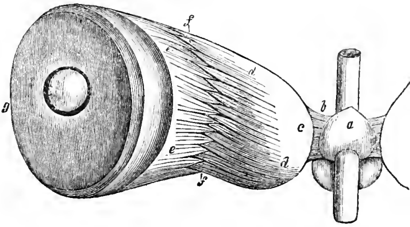
Fig. 424.



Organ of vision, together with the optic nerve and supra-œsophageal ganglion in the loligo, much magnified. (From a dissection by the writer.)

a, supra-œsophageal ganglion; *b*, optic nerve; *c*, optic ganglion; *d, d*, one series of filaments springing from the edge of the ganglion; *e, e*, second series of filaments derived from the opposite edge of the ganglion, and in this view visible near their termination *only*; *f, f*, points at which the filaments of the two series decussate; *g*, ball of the eye.

after making their way to the eye-ball, and perforating the sclerotic, terminate in the retina. These filaments are arranged at their origin in a double linear series, each series streaming forth from one of the opposite margins of the ganglion. After becoming free of the ganglion the filaments of each series approach those of the other series, and a most perfect and regular interlacement of the two sets ensues; so completely do they decussate that either half of the retina is formed by filaments which spring from the *opposite* edge of the ganglion; those filaments which shoot out from the *anterior* margin of that body terminating in, and actually forming, the *posterior* moiety of the retina, and vice versâ.

The reciprocal interlacement of these nervous filaments reminds one of the manner in which the two series of threads in a weaver's loom (technically called the woof and the warp), cross each other; this illustration is exact, for the interlacement of the threads in the one case is not more perfect or regular than that of the nervous filaments in the other.

The writer is indebted to his colleague, Dr. Power, for a knowledge of this curious arrangement, which was discovered by that gentleman while inspecting a preparation of the nervous system in the loligo made by the writer, and which still exists in the Museum of the Richmond Hospital School, Dublin.

Subsequent dissections have proved satisfactorily that the decussation in question occurs invariably in the loligo, and that in the octopus, which exhibits close affinity to the loligo, the same arrangement prevails. In the sepia officinalis the optic ganglion is reniform, and its filaments come off in a double series, as in the loligo; the majority of the filaments decussate after the same manner as that above described in the other two species, but some of the extreme filaments of each series pass in a direct course to the retina, without exhibiting any decussation.

The peculiar disposition of the optic filaments in these cephalopods was unnoticed until the publication of Dr. Power's paper on the subject in the "Dublin Journal of Medical Science," —an omission the more surprising, as accurate descriptions of the eye in this class of animals have appeared from some of the ablest anatomists.

Swammerdam long ago described and delineated the optic ganglion of the sepia officinalis, but without making any mention of the intercrossing of the filaments which emanate from that body. Cuvier, in his memoir on the Mollusca, describes the eye of the poulpe (octopus) with great accuracy, but makes no allusion to the decussation in question; and in the most recent descriptions of the cephalopods the same omission occurs.

The above discovery seemed at first likely to afford an explanation of the problem so difficult of solution, namely, the well-known fact, that objects appear *erect* to a spectator although their images on the retina are inverted; and for some highly ingenious observations tending to elucidate this obscure question, the reader is referred to the paper by Dr. Power, already quoted; it may be stated, however, that many difficulties remain to be removed before such an explanation can be received, for

1. The filaments of the optic nerve of the loligo have not as yet been traced back to the central masses of the nervous system, and there can therefore be no certainty that they preserve in the first part of their course the same relative positions which they are known to maintain in the interval between the optic ganglion and point of decussation.

2. In vision the object is known to be *wholly* reversed in the image on the retina; for example, that which is *above* in the object is *below* in the image, and vice versâ; and that which is to the *right* in the object is to the *left* in the image, and vice versâ; now, although the decussation in question might possibly explain the correct appreciation of an object whose image is reversed in *one* particular direction (say from above downwards), it never can fully explain the correct impression made by an object of which the image is reversed in *all* directions simultaneously.

3. In order that this explanation may apply to human vision, the same interlacement of filaments must first be demonstrated in the optic nerve of man, a task which has not as yet been accomplished.

Optic nerves of the compound eyes of Insects.

These nerves are excessively large and appear proportional to the size of the organs of vision in the Insect.

Each nerve on arriving at the eye swells out into a bulb, which is convex and varies considerably in dimensions in different species; this bulb in general represents a segment of a sphere, and from its surface nervous filaments in immense numbers arise and diverge like the radii of a circle. Several thousand of these filaments have been counted in a single nerve; each of them is connected by its distal extremity to the apex of a small conical transparent body interposed between the filament and the corresponding facet of the cornea, but the most striking peculiarity of the nerve is found in the perfect isolation of each of these filaments by the interposition of pigment.

The pigment is variable in colour, being sometimes light, at others dark; it may be nearly black, dark violet, dark blue, purple, brown, brownish yellow, light yellow, or green, and sometimes several layers of different colours lie one over the other; the pigment extends from the bulb of the nerve to the cornea; it surrounds each filament and separates it completely from adjacent filaments.

The effect of this disposition is to isolate the rays of light incident on each filament, and to prevent the transmission of all rays except such as fall in the direction of the axis of the filaments; since all oblique rays must of necessity impinge upon the colouring matter and be in consequence absorbed.

The reader is referred to the article Insecta for further details concerning the optic nerve in these animals.

Plaited optic nerve.

The optic nerve in some animals exhibits a peculiar plaited appearance; this condition occurs in greatest perfection in certain fishes, and in many birds a somewhat similar organization may be detected, though not at all so perfectly as in the fish tribes.

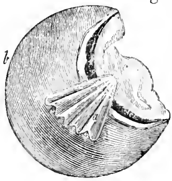
When the plaiting prevails in perfection, the nerve consists essentially of a thin membrane folded on itself exactly like a closed fan or a plaited frill; but the arrangement referred to is not at first sight apparent, particularly if the nerve be inspected in that part of its course only which is external to the cranial cavity, for there the neurilema is so thick, dense, and tough, that a correct estimate of the disposition of the nervous structure cannot be formed until this investment has been removed.

Deprived of its neurilema, the nerve seems to consist of a number of parallel laminæ placed in juxta-position; on closer examination these laminæ turn out to be continuous with each other at their edges, and by a little care the nerve can be unfolded into a membrane of which the breadth is proportional to the number and depth of the original laminæ.

When the plaited condition is perfect, it prevails along the entire length of the optic nerve, becoming manifest at its cerebral attachment, and continuing to the eye-ball; even the retina seems to participate in the same disposition, as folds or plaits are observable on the surface of that nervous expansion; and in certain fish the optic lobes themselves present a similar organization, for the walls of the cavities which these tubercles contain are in some instances covered with laminæ.

The plaiting must be considered an essential attribute of the nervous substance and totally independent of the neurilematous investment, for this disposition of the nervous material occurs occasionally in the optic lobes and retina, structures which are devoid of neurilema. (*Fig.* 425.)

Fig. 425.



Plaited optic nerve of a Mullet. (From nature.)

a, optic nerve deprived of neurilema, exhibiting the plaited disposition; *b*, sclerotic coat of the eye through which the nerve is passing; *c*, retina, in which the nerve terminates.

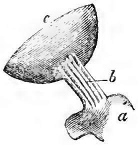
Laminated optic nerve.

In certain birds the optic nerve is laminated and bears a close resemblance to the plaited condition just described.

In these birds a careful examination of the nerve is required for the discovery of its true texture, for the neurilema (endowed with uncommon strength) adheres so firmly to the nervous structure that without a careful dissection its laminæ elude observation.

When viewed on one side the nerve seems perfectly smooth, but on the opposite side numerous laminæ may be distinctly observed; these are parallel to each other, and run along the nerve in the longitudinal direction: they are of considerable depth and variable thickness; they are applied closely to each other, being separated by thin processes of neurilema only, and altogether (their straight course excepted) this arrangement bears a striking similarity to the disposition of the laminæ on the human cerebellum. A short section of the nerve divested of its neurilema is not unlike a closed book, the laminæ representing the leaves, and the opposite smooth surface of the nerve bearing a resemblance to the back and cover of the book. The laminated optic nerve of the bird does not admit of being unfolded into a flat membrane, a proceeding which can be accomplished with care in the plaited optic nerve of the fish: and in birds the laminated structure occurs in that part of the nerve only which is in front of the chiasma; in its cerebral extremity no such organization prevails. (*Fig.* 426.)

Fig. 426.



Laminated optic nerve of an Eagle. (From nature.)

a, chiasma; *b*, optic nerve divested of neurilema and exhibiting laminæ on one surface; *c*, sclerotic coat.

Desmoulins, who has paid the greatest attention to these varieties, inferred as the result of his extensive researches, that the plaited arrangement of the optic nerve in fish, and its laminated condition in birds bears proportion to the perfection of vision in the animals under consideration; for those birds which are endowed with the most powerful piercing sight possess the laminated structure at a maximum of developement. For example, birds of prey, such as the eagle, the falcon, and the kite, evince an acuteness of this faculty truly surprising; from heights in the atmosphere, at which they are themselves almost invisible, they discover their prey on the ground and pounce on it with the most unerring certainty, whilst at the trifling distance of a few yards other animals recognise such objects with difficulty: now birds of this class afford the most perfect specimens of the laminated optic nerve. It is further stated on the same authority that birds which at short distances possess remarkably quick and accurate powers of vision (more especially when in such cases this faculty is exercised in media of different degrees of density) are also provided with laminated optic nerves, and that most fish in which the plaited optic nerves occur are of predacious habits, and consequently require powerful organs of vision just as the birds of like propensities.

The writer has examined the optic nerves in the stork, kingfisher, eagle, &c., and in them, as well as in all the fishes which have fallen within his reach, his dissections have amply verified the anatomical descriptions given by Desmoulins.

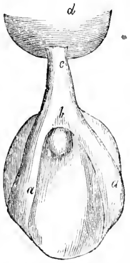
It is difficult to explain the superior sensibility supposed to be thus conferred on the optic nerve; but the more obvious effect of this organization is to increase the *surface* of the nervous material. A similar contrivance is at times resorted to in the nervous centres, as is exemplified in the cerebral hemispheres; these masses in the higher and more intelligent animals being covered with large convolutions and deep sulci, while in the lower classes they are smooth and consequently possess a superficies of limited extent.

Optic nerve in that form of monstrosity known by the varied appellations of "Cyclops," "Fœtus à trompe," "Monops," "Rinencephale," &c. &c.

The abnormal anatomy of the optic nerve is not in strictness comprised within the scope of the present article, but nevertheless a brief description of the above malformation will probably not be considered out of place.

A *single* eye placed in the middle line of the forehead, and in general a trunk or proboscis growing immediately above this solitary organ of vision, constitute the most striking *apparent* anomalies in monsters of this class. The writer is indebted to Dr. Johnson, Master of the Dublin Lying-in Hospital, for permission to dissect a specimen of this species of monstrosity in the human subject, and he has obtained through the kindness of Dr. William Wilson Campbell, (formerly assistant in the same establishment,) the particulars of another similar case examined by that gentleman in the year 1834. The annexed wood-cut (*fig.* 427) gives a faithful representation of the optic nerve in the preparations dissected by the writer and Dr. Campbell; and it agrees exactly with the appearances found by Geoffroy Saint-Hilaire, in the cases which fell under his observation. The tractus optici present a very natural appearance, being two in number, and perfectly normal in their cerebral attachments, course, and relations, &c. The chiasma is contracted in front, and from it, only a single optic nerve proceeds; this passes directly forwards to the back of the eye-ball, where it penetrates the sclerotic and terminates in the retina.

Fig. 427.



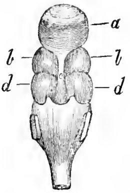
Optic nerve in a human Cyclops. (From a dissection by the writer.)

a, a, tractus opticus of either side; *b,* chiasma; *c,* single optic nerve; *d,* sclerotic coat of the eye perforated by the optic nerve.

Fig. 428 represents the encephalon, optic nerve, and organ of vision in a kitten at the full period of gestation, (the subject of the same form of monstrosity,) which lately came into the writer's possession: the preparation is preserved in the Museum of the Richmond Hospital School, Dublin. In all essential particulars this specimen bears the closest resemblance to the human monsters of which the dissection has just been described.

The fundamental defect in these monstrous

Fig. 428.



Brain and organ of vision of a Cyclops kitten, at the full period of gestation. Seen from below. (Natural size.)

a, organ of vision, single, and of great dimensions; *b, b,* cerebral hemispheres seen from below; *d, d,* tubercula quadrigemina; *c,* optic nerve, single, and of great size.

fœtuses consists in the total absence of the organ of smell, in consequence of which deficiency the symmetrical organs at either side become united in the middle line and actually engrafted upon each other: the *two* eyes are conjoined so as to form but a single organ of vision, and the very same metamorphosis occurs in the *two* orbits, the *two* optic foramina, the *two* optic nerves, &c.

That this is the rationale can scarcely admit of doubt, since in some parts of the organs the fusion remains incomplete; thus *two* crystalline lenses still exist in the interior of the solitary eye-ball: a double set of muscles with their corresponding nerves are provided for the globe of the eye; and *four* eye-lids protect the organ in front, causing the aperture of the lids to assume a quadrangular form.

General developement of the optic nerves in the higher classes of animals.

Fish.—In fish as a general rule these nerves are highly developed, and exhibit a marked preponderance in size when contrasted with the corresponding nerves in many animals holding a more exalted position upon the scale. This may be explained by the nature of the medium which the fish inhabits; for some of the light incident on the surface of the water is reflected, and another part, after penetrating the water, becomes absorbed, in consequence of the continual disturbance to which the transparency of this fluid is subject; so that fishes necessarily require a greater developement of visual apparatus than would suffice *land* animals for an equal amount of vision.

Birds.—In birds the sense of sight exists in great perfection, and the optic nerves exhibit corresponding developement.

Mammalia.—In Mammalia the faculty of vision ceases to preponderate, and accordingly the proportions of the optic nerves in this class are no longer excessive.

Many facts in comparative anatomy warrant the conclusion that the senses of smell and vision are at times supplemental to each other; for example, the mole either possesses no optic nerve, or if any such exist it is so diminutive as to be most difficult of recognition, but the olfactory lobes of the brain and the whole olfactory apparatus of the animal exist in great perfection, and its subterranean habits enable it to turn this latter function to account, whilst a highly finished organ of vision would have been an useless appendage. In certain fish which frequent the mud or slimy waters (as for instance the eels), the visual apparatus is poorly developed, and the optic nerves are particularly small; but the olfactory nerves preponderate, and there can be little doubt that the superiority of the sense of smell in them serves in great measure to supersede the necessity for highly-wrought organs of vision, and in probably the majority of the Mammalia the olfactory nerves preponderate in size over the optic, but the corresponding faculty by its acuteness makes amends for any inferiority in vision. Thus the keen scent of many Carnivora renders the eye of secondary importance in the pursuit of their prey, and the vegetable feeders are much indebted to the perfection of their sense of smell for the discrimination they evince in their choice of nutriment.

FUNCTIONS OF THE OPTIC NERVE.

The optic nerves when present are essential to vision.

In all animals which possess optic nerves they must be considered essential to vision, for diseases which destroy the organization of the "second pair" invariably deprive the organs of sight of their sensibility to luminous impressions; and were other proof wanting, the experiments instituted of late years by Magendie, Mayo, and others, would afford sufficient evidence of the *special* function of the nerves in question. Magendie found that division of either optic nerve in front of the chiasma was instantaneously followed by complete loss of vision in the corresponding eye of the animal submitted to the experiment; and when *both* optic nerves were thus divided *total* blindness ensued, and no means which could subsequently be devised for concentrating light upon the eye appeared to excite in the retina the slightest sensibility to its accustomed stimulus.

Although the foregoing facts would warrant the conclusion that *the only* nerves capable of endowing the eyes with their *special* sensibility are the *optic*, nevertheless many considerations favour the presumption that the fifth pair exert direct influence on the sense of sight, so much so that some have considered these nerves *essential* to vision, whilst others have even supposed that the faculty in question may be maintained through the agency of the fifth nerves *alone*.

In those animals which possess special optic nerves, the fifth pair are totally inadequate to support vision.

There are no facts on record to prove the possibility of such animals continuing to see after destruction of the second pair. The experiments already cited may be looked on as conclusive, and those performed by Magendie to show that divison of the fifth nerves within the cranium in living animals produces blindness, can never justify physiologists in the belief that the "trifacial" may endow the eyes with their *special* sensibility.

Certain facts furnished by the comparative anatomy of the second and fifth pairs have been from time to time adduced to shew that the fifth in the human subject possesses this power. Thus it is stated on good authority, that the common Mole, the Proteus anguinus, the Mus Capensis, the Chrysochlore, the Mus typhlus, and the Sorex araneus, in which organs of vision occur, are not provided with special optic nerves, and that in them the fifth pair furnishes the only nerve which the rudimental eye receives. It is argued from these data (and Serres would seem to be one of the ablest advocates for this view) that a branch of the fifth nerve assumes in such cases the functions of the optic, becoming endowed with special sensibility to light, and that therefore from analogy the ophthalmic division of the fifth in *man* may be presumed to possess similar properties.

Conclusions arrived at by such reasoning should be received with caution in the absence of more direct proofs; the weight to which they are entitled has been already fully discussed under the article FIFTH PAIR OF NERVES, and reference is made to that article for further particulars touching this interesting topic. The writer fully concurs in the views therein advocated, and feels disposed to attribute little value to arguments founded, as they appear to be, on imperfect analogies. The cases of the human subject and the animals specified are essentially dissimilar; the presence of a special optic in the one case, and its absence in the others, destroys their parallelism, and may create important differences in the functions of accessory nerves; and, moreover, the little knowledge we possess of the nature and amount of vision enjoyed by animals in which special optic nerves are wanting, should make us hesitate to argue from them to the human subject.

That the fifth pair exercise some influence over vision can scarcely be denied, but the nature and amount of this influence are not so easily determined, and have probably been much exaggerated.

In the present state of their knowledge physiologists have not sufficient proof that in the higher animals the influence of the fifth pair is absolutely essential to sight.

Magendie discovered that the section of the fifth nerve on both sides within the cranium of a living animal greatly impairs, if it does not actually annihilate vision, and such a result *seems*, no doubt, to argue that the faculty of sight has a *necessary* dependence on the integrity of the "trifacial nerves," but the experiment when critically examined will appear not to warrant such an inference; it demonstrates that so rude an injury inflicted on the nervous centres deprives an animal of one of its faculties, and this might have been anticipated on general principles; but it does not prove that the loss of the faculty depends on the injury to the fifth nerves *alone*. In such a destructive proceeding there can be no assurance that the fifth pair have been the *only* parts of importance mutilated; the contrary is by much the more probable presumption, and, therefore, the conclusion "that the fifth nerves are essentially necessary to vision" is not fairly deducible from the experiment. But farther, the facts (detailed even as they are by Magendie) suffice to show, that the eye may continue sensible to luminous impressions *after complete division of the fifth pair*, for according to his own account, "the eye of the rabbit on sudden exposure to the sun's rays, after the fifth pair had been divided, was still sensible to strong solar light; and the effect was more marked when a lens was used to test its sensibility."

Mayo's experiments on pigeons afford still more convincing proof of the ability of the optic nerve, *unaided by the fifth*, to maintain the special sensibility of the eye; this physiologist succeeded in dividing the fifth nerve within the cranium of a living pigeon (leaving the optic uninjured,) *without rendering the retina insensible to light.*

The results of pathological observations on man furnish also abundant evidence that vision *may continue* after disease has destroyed the fifth nerve. Opportunities do not often occur of bringing this to the test of dissection, for in most of these cases changes of structure involve other parts of the nervous centres simultaneously with the fifth nerve, and so deprive them of their greatest value; and the destructive inflammation of the eye-ball, which so constantly accompanies morbid alterations of the fifth pair, is another fruitful source of embarrassment in attempts to investigate their history, but even a few well-attested observations are amply sufficient to establish a negative proof. Müller cites a case of disease involving the whole trunk of the fifth nerve of the left side, in which insensibility of the entire left side of the head and the corresponding side of the tongue and eye, occurred, *while vision remained perfect;* and in the article FIFTH PAIR OF NERVES, other similar examples are related.

The conjecture that the fifth pair is essential to vision receives probably its strongest support from the occasional results of injuries to certain branches of that nerve, for numerous cases are on record in which wounds or contusions of its frontal twigs have been followed by blindness, and the same unfortunate event has resulted (though rarely) from irritations affecting some of its other branches. Thus, Mr. Travers has known amaurosis to originate from irritation of the dental nerves. He says, "I have seen an incipient amaurosis arrested by the extraction of a diseased tooth, when the delay of a similar operation had occasioned gutta serena on the opposite side two years before." And Professor Galenzowski of Wilna "observed severe neuralgia and blindness produced by a splinter of wood becoming entangled in a diseased tooth, and these symptoms were cured by the extraction of the tooth together with the offending material."

The value of such facts as these in assisting physiologists to determine the influence exerted by the fifth nerve over vision, appears to have been much overrated; for in a large proportion of these cases it may be inferred with great probability that the same injury which affected the supra-orbital nerves exerted also pernicious influence on the deeper seated contents of the orbit, and that the optic nerve, or retina, or even the brain itself participated in the effects of the violence, although from the more superficial position and greater exposure to danger of the frontal branches of the fifth, they alone were believed to have suffered. This explanation will undoubtedly not apply to cases in which blindness has been produced by very trivial injuries, such as simple incised wounds or punctures of the nerves in question; but nevertheless the weight of evidence which these latter cases would seem to afford is much diminished by the consideration that loss of sight has likewise ensued from injuries and affections of other nerves, to which, while healthy, no participation in the support of vision can be conceded. For example, Dr. Jacob recites the case of an officer in whom amaurosis occurred in consequence of injury inflicted by a ball on some branches of the portio dura;* and irritations in the digestive organs (dyspeptic disturbance of the stomach more especially) are well known to produce at times amaurotic symptoms. Now, although these facts unquestionably establish the existence of curious *pathological* affinities between the nerves of the part thus irritated and those which are subservient to vision, no physiologist would be hardy enough to infer from such premises that the facial nerve, the par vagum, or those which supply the intestinal tract, exercise in the *normal* state any control over the faculty of sight.

If, in addition to these considerations, it be recollected that blindness occurs only as an *occasional* consequence of injuries to the frontal nerves, and that loss of vision is found to ensue *very rarely* from the irritations to which other branches of the fifth are so peculiarly liable, the importance of such cases in determining the question must be still further lessened. The observations of Dr. Jacob on this subject appear to the writer so apposite that he is induced to insert them. This gentleman writes, "Blindness does not seem to have followed any of the operations formerly so much practised of dividing the branches of this nerve, and in some of the worst cases of that form of neuralgia called tic douloureux, vision is not impaired. Moreover, thousands of children suffer from dentition and thousands of adults from tooth-ache, yet none of these become blind in consequence."†

The coincidence of loss of sight with injuries or irritations affecting branches of the fifth nerve, admits of explanation on other principles without assuming the fifth to be *essential* to vision; the hypothesis that in such cases reflex irritation becomes propagated from the parts primarily affected through the nervous centres to the optic nerve, seems in the present state of physiological science sufficiently plausible; for while it applies to cases of amaurosis resulting from abnormal conditions of *other* peripheral branches of the nerve as well as its ophthalmic division, it also affords a solution of the still more obscure dependence of the same disease on irritations in remote organs.

The experiments of Magendie, confirmed as they have been by pathological observations,

* Cyclopædia of Practical Medicine, art. AMAUROSIS.

† On Paralytic Neuralgia and other Nervous Diseases of the Eye, by Arthur Jacob, M.D.

justify the inference that the fifth nerve endows the eye with its *general* sensibility, and also exerts some influence over the nutrition of that organ.

This distinguished physiologist divided the fifth nerve within the cranium of an animal and found the tactile sensibility of the surface of the eye completely abolished by the experiment; opacity, ulceration, and sloughing of the cornea, followed by expulsion of the humours, and total destruction of the eye subsequently ensued; and nearly the same results have been observed to occur in the human subject from disease affecting the fifth nerve within the cranium. It must be perfectly obvious, however, that these facts have no bearing upon the question more immediately under discussion.

An impartial review of this highly interesting question leads to the conviction that notwithstanding the great plausibility of the arguments by which the *contrary* view has been sustained, there is as yet no evidence that in man any other nerve than the optic enjoys special sensibility to light.

Ordinary tactile sensibility.—Although the optic nerves are endowed with such acute sensibility to the influence of light, they would seem to possess little *ordinary tactile* sensibility,—a circumstance the more surprising, as it is difficult to imagine any impressions more delicate than those of light; and where nerves evince such exquisite susceptibility of excitement from the stimulus of that imponderable agent, an equal obedience to those rougher stimulants which produce such marked effects on the common sentient nerves might at least be expected.

Magendie infers from his experiments on living rabbits that the retina in them is not susceptible of pain from mechanical irritation; so much so, that puncturing or tearing that nervous expansion appeared to him to cause these animals no sort of suffering.* Precisely the same results followed from injuries inflicted by him on the retina in fish and reptiles, although in birds, cats, and dogs similar experiments seemed to create some uneasiness. This physiologist asserts that the human retina *also* is devoid of ordinary tactile sensibility, for in operating for cataract he has proved that the membrane in question exhibits little if any susceptibility of pain.

His experiments were likewise extended to the optic nerves; and in the course of his investigations frequent opportunities were afforded for testing the comparative sensibility of the second and fifth pairs. In all the mammalia, whether the injury was inflicted in front of or behind the chiasma, the second pair seemed quite insensible to mechanical irritation; and whenever the slightest disturbance affected the fifth nerve, the animal, by its cries and struggles, immediately manifested the most acute sufferings.

The phenomena noticed in extirpation of the human eye are favourable to the same views, for division of the optic nerve in this operation is not attended with the agonizing torture which an equal amount of injury to a nerve of the same dimensions endowed with common sensibility would unavoidably produce. This fact should have some weight with physiologists in their attempts to form a just estimate of the properties of the nerve under consideration, although the results of such observations are inconclusive; for in many cases of extirpation of the organ the optic nerve is itself diseased, and under such circumstances it would be unfair to argue from the *known* effects of injuries on a *diseased* structure, to the *probable* effects of injuries on the same structure *when healthy.*

The optic nerve is not singular in its insensibility to pain from mechanical irritation, for experiments on other nerves of special sense countenance the belief that some of them labour under the same disability. Magendie laid bare the olfactory of a dog, and the animal did not manifest the slightest pain when the nerve was compressed, pinched, or even torn; and when the auditory of a rabbit was subjected to similar rough treatment at his hands, the animal afforded no indication of suffering.*

The specific stimulants of the organs of sense act however at times so intensely as to produce *painfully* disagreeable impressions on their respective organs, and it therefore becomes difficult to reconcile, with the foregoing statements, facts such as the following, which apparently favour the opinion that the optic as well as other nerves of special sense possess *common* sensibility. "An intense light dazzles the eye so as to become actually insupportable. A harsh or discordant sound produces a most distressing impression on the organ of hearing; and certain odours are disgusting and intolerable to the pituitary membrane."

In estimating the weight to which these latter facts are entitled, it should be recollected that the above sensations still preserve their specific characters, no matter how intensely disagreeable they become: thus light, although sufficiently brilliant to dazzle the retina, still continues to be a luminous impression, and in like manner sonorous vibrations and odours, though actually offensive to their respective organs, are still nothing more than sounds and scents. So that on the whole, however questionable may be the propriety of such experimental zeal as would induce a French physiologist to test the sensibility of the human retina in operations for cataract, the general proposition that the optic nerve in man and the higher animals enjoys little, if any, tactile sensibility, seems pretty well established.

Effects of stimulants.—Although the optic nerve betrays little indication of pain in consequence of injuries, nevertheless mechanical and other stimulants produce upon it peculiar effects: mechanical injuries and irritants arouse its *special sensibility* instead of exciting painful sensations—their ordinary effects on common sentient nerves.

* Journal de Physiologie, t. iv.

* Journal de Physiologie, t. iv.

For example: firm pressure applied to the globe of the eye when the lids are closed and light excluded, gives rise to the sensation of luminous spectra which present different colours. Concussion of the eye-ball is often followed by the same results: division of the optic nerve in extirpation of the organ of vision generally causes the patient to perceive a great light; and an electric current transmitted through the optic nerve, or its immediate vicinity, seems to produce a flash of light. The second pair, in having their *special* sensibility excited by such varied stimulants, merely conform to the laws by which other nerves of special sense are governed; for electricity applied to these nerves *severally* may be made in each case to elicit the peculiar sensibility of the nerve which happens to be the subject of the experiment: in the optic nerve it produces the sensation of a flash of light; in the auditory it excites a loud sound; in the gustatory it gives rise to a peculiar taste; in the olfactory it developes a particular smell; and in the common sentient nerves it causes painful sensations. In like manner a blow may occasion the optic nerve to flash fire, the auditory nerve to hear sounds, the common sensitive nerves to feel pain; and more examples might be added to this catalogue.

The nerves of special sense seem in general to be endowed with but one determinate sort of sensibility; and though this is commonly excited by a specific stimulus *only*, it may be elicited occasionally *by other means*.

Excito-motory properties.—The optic nerve is one of those paths through which incident impressions are propagated so as to excite reflex motions. The impression of light on the retina is instantaneously followed by contraction of the pupil, a phenomenon indicative of reflex motion developed in the iris; and the sudden closure of the eye-lids under the influence of a strong light or a threatened blow is also a familiar example of reflex motion produced by impressions upon the terminal expansion of the optic nerve.

Lambert, Fontana, and Caldani, have demonstrated that the optic nerve is the channel through which the incident impression travels in order to excite reflex motion in the iris. In their experiments, rays of light transmitted through a hole in a sheet of paper, and by this contrivance conveyed through the pupil *directly* to the retina, produced immediate motion of the iris; but when the light was allowed to impinge upon the iris *alone* without reaching the retina, *no* contraction of the pupil ensued.

Mayo's experiments on pigeons taken in connection with the foregoing facts appear particularly instructive, proving as they do that in the bird, irritation propagated along the optic nerve in a centripetal direction may excite reflex motion in the iris. When the optic nerves were divided within the cranial cavity of a living pigeon by Mayo, the pupils became fully dilated and were no longer obedient to luminous impressions even when dazzling light was admitted into the eyes. When a pigeon was decapitated by the same experimentalist, and its optic nerves subsequently divided within the cranial cavity, irritation of that portion of the divided nerves which continued in connection with the *eye* produced no effect on the iris; but contraction of the pupil immediately ensued when the *other* extremity of the nerves, viz. that which retained its connection with *the brain*, was irritated.

In general the reflex motion is developed in the iris of the *same eye* on which the impression is incident, or in other words light falling on the *right* retina produces in general contraction of the *right* pupil and not of the left, and vice versâ; but it sometimes happens that an impression propagated along one optic nerve (for instance the *right*) *may* cause the reflex phenomena to appear in the iris of the other eye (viz. the *left*).

Certain forms of amaurosis in which the disease affects *but one* eye while the other continues healthy will serve for illustration.

In such cases it occasionally happens that little or no difference in the size of the two pupils can be detected so long as both eyes remain exposed to the light, the iris of the diseased organ contracting and dilating simultaneously with that of its healthy neighbour; but as soon as the lids of the sound eye are closed, the pupil of the amaurotic eye becomes dilated, and the most intense light admitted into this diseased organ takes no effect on the iris, now become perfectly motionless.

The explanation of these phenomena is found in the preceding proposition; so long as the *healthy* eye continues exposed to light, the impression falling on a *sound* retina excites reflex motion in the pupils of both eyes, as well the amaurotic as the sound; but when the light is excluded from the healthy retina, the influence of that agent upon the *diseased retina* of the other eye has no longer the power to excite reflex motions.

The exercise of these excito-motory properties of the optic nerve is generally accompanied with excitement of its *special* sensibility; thus a person is *in general* conscious of the luminous impression, or, in other words, he sees the light which causes contraction of his pupil; but the reflex phenomena *may* be manifested by the iris, although the incident impression pass unnoticed by the individual.

In certain cases of general insensibility (as, for example, concussion occasionally) the pupil contracts upon the admission of light while the patient remains perfectly unconscious, and something similar seems to occur at times even in health; for the iris varies its dimensions with each successive change in the volume and intensity of the light, although from inattention we do not perceive these trifling changes. Some degree of attention appears requisite in order that weak or transitory impressions should arouse the special sensibility of the optic nerves, whereas attention is not a condition essential to the production of reflex phenomena.

Mayo's experiments here again admit of application; he found that in decapitated pigeons in which the optic nerves were subsequently divided, irritation of the cerebral extremity of the cut nerve produced contraction of the pupil, although under the circumstances the animal could not have been conscious of such irritation.

Radiated or sympathetic sensations.

The optic nerve participates in a class of obscure sensations to which a brief allusion may be here permitted; these are called radiated or sympathetic sensations; they occur occasionally in health, though they are more frequently symptomatic of disease or irritation elsewhere situated, and as they are likewise manifested by other nerves it would be erroneous to consider them *peculiar* to the optic. The phenomena to which allusion is made are for the most part transitory affections of sensitive nerves which do not seem to depend on any *direct* impression made upon the nerve affected, but rather to be produced by causes which act on other (generally distant) parts of the system.

The following will serve as examples of the affections under consideration.

A discordant sound, such as that produced by setting a saw or scratching glass, gives rise to shuddering, or a sensation as if water were dropping over the surface. Tickling the soles of the feet occasions general sensations of the most disagreeable nature; and the impression of a strong light on the eye is often followed by a sense of irritation in the nose, with violent sneezing.

Similar affections of the optic nerve will readily occur to the reader's recollection; thus various forms and degrees of temporary insensibility or excitement of the retina, which are known to depend on gastric disturbance, belong to this category, and many other such instances might be adduced.

Facts, such as the foregoing, have long been familiar to physiologists; but to account for them seems still to be a matter of difficulty. The supposition that the connections of the sympathetic with the nerves affected explain the problem is far from satisfactory; the most plausible theory is that which supposes the primary irritation to be propagated in a centripetal direction along the nerves of the part to the cerebro-spinal centres, and thence reflected upon the roots of those nerves in which the sensations are developed, in somewhat the same way that excito-motory impressions on nerves come to produce reflex motions; the difference in the two cases amounting to this, that in the one the primary impression reacts upon *motor* nerves, giving rise to reflex *motions*, in the other on *sensitive* nerves causing thereby reflex *sensations*.

Though this may be the true explanation, it is nevertheless not perfectly satisfactory, for it does not shew *why* the reflex irritation should be prone to fall on one sensitive nerve in preference to another, yet the optic is known in such cases to suffer more frequently than the auditory or olfactory.

ORBIT. (*Orbis*, any thing round: Fr. *l'orbite;* Germ. *Augenhöhle.*)—In the present article it is intended to describe, first, the bony framework of the orbit; secondly, the contents* of the orbit in the order in which they are exposed by a dissection from the roof to the floor of the cavity; and, lastly, to give some account of the action of the muscles contained in the orbit and inserted into the upper lid and globe of the eye.

The orbits are two in number, situated at the anterior and upper part of the face. They have the form of quadrangular pyramids, the bases of which are directed forwards and outwards, the apices backwards and inwards. Each orbit presents for examination four walls, four angles, formed by the meeting of the walls, a base, and an apex.

The *superior wall* or roof is concave and directed downwards and slightly forwards. It is chiefly formed by the orbital plate of the frontal bone; at the posterior part to a slight extent by the lesser wing of the sphenoid. It presents the suture between the orbital plate of the frontal and the lesser wing of the sphenoid, and anteriorly on the outer side, the lachrymal fossa, which receives a gland of the same name;

* The relative anatomy only of these parts will be given in this article, a special description of the Eye and Lachrymal Organs having already been given.

on the inner side a depression for the insertion of a pulley, through which runs the tendon of the superior oblique muscle.

The *inferior wall* or *floor* is less extensive than the roof, and is directed upwards, outwards, and forwards. It is formed chiefly by the orbital plate of the superior maxillary bone, in front of this by the orbital process of the malar, and at the posterior part to a slight extent by the orbital process of the palate bone. It presents a suture marking the union of the malar with the maxillary, and of the maxillary with the palate bone; about the middle of the floor is the infra-orbital groove, which passes forwards and becomes the infra-orbital canal.

The *external wall* is directed inwards, forwards, and slightly upwards; it is formed in front by the orbital process of the malar, and posteriorly by the orbital surface of the greater wing of the sphenoid. It presents a vertical suture at the junction of the malar with the sphenoid bone, and the orifices of some small canals which open externally in the temporal fossa, and on the facial surface of the malar bone; some of these canals transmit filaments of nerves from the lachrymal branch of the ophthalmic, and from the superior maxillary nerve.

The *internal wall* is directed outwards, and slightly forwards and upwards: it is formed chiefly by the os planum of the ethmoid, in front of this by the lachrymal, and behind by the side of the body of the sphenoid. It presents a vertical suture between the lachrymal bone and the ethmoid, and another between the latter bone and the sphenoid; and anteriorly a vertical groove which lodges the lachrymal sac.

Angles.—The *superior* and *external* angle formed by the junction of the superior with the external wall presents posteriorly the sphenoidal fissure, sometimes called foramen lacerum anterius; in front of this a horizontal suture at the junction of the orbital plate of the sphenoid with the orbital plate of the frontal bone, and anterior to this the junction of the malar with the frontal bone.

The *superior* and *internal* angle formed by the meeting of the superior and internal walls presents a suture between the os planum of the ethmoid and the orbital plate of the frontal; in this suture are two small holes, the anterior and posterior internal orbital holes; the anterior transmits the nasal branch of the ophthalmic nerve, and the anterior ethmoidal artery; the posterior gives passage to the posterior ethmoidal artery; in front of the last-mentioned suture is another between the lachrymal and frontal bones.

The *inferior* and *external* angle, formed by the meeting of the inferior and external walls, presents posteriorly the spheno-maxillary fissure, which is bounded externally by the orbital plate of the sphenoid, internally by the orbital plates of the superior maxillary and palate bones, and in front usually by the orbital process of the malar bone, but occasionally by the junction of the orbital plates of the superior maxillary and sphenoid bones at this point.

The *inferior* and *internal* angle formed by the meeting of the inferior and internal walls presents a continuous horizontal suture, which in front connects the maxillary bone with the lachrymal, behind this the maxillary with the ethmoid, and still more posteriorly the palate bone with the ethmoid.

The *base* or *circumference* is of an irregular quadrilateral form with curved sides and rounded angles; it inclines obliquely from within outwards. It is formed above by the supra-orbital arch of the frontal bone, on the outer side by the external angular process of the frontal and by part of the orbital border of the malar; *below* by the continuation of the orbital border of the malar, and by the corresponding orbital border of the superior maxillary bone; on the inner side it is completed by the nasal process of the superior maxillary, and the internal angular process of the frontal bone. At the junction of the middle with the inner third of the supra-orbital arch is the supra-orbital notch or foramen, which transmits the frontal nerve and vessels. There are three sutures in the margin of the orbit, one between the frontal and malar, a second between the frontal and superior maxillary, and a third between the malar and superior maxillary bones. At the junction of the lower with the inner border of the orbit is a small tubercle, the *lachrymal tubercle*, which is sometimes pointed out as a guide in the operation for fistula lachrymalis, but it is seldom very prominent even in the bare bone, and it could scarcely be detected through the tumefaction consequent on obstruction of the lachrymal duct. The lachrymal groove is immediately behind the internal margin of the orbit.

In the *apex* of the orbit is the optic foramen situated between the two roots of the lesser wing of the sphenoid bone; the direction of the optic hole is backwards and inwards towards the centre of the sella Turcica. The inferior root of the lesser wing of the sphenoid, which separates the optic hole from the sphenoidal fissure, presents anteriorly a small tubercle which gives origin to the common tendon of the internal, external, and inferior recti muscles.

Dissection of the orbit.—Having removed the skull-cap and brain, the roof of the orbit may be taken away by two vertical cuts with a saw, the inner cut extending from a point just external to the internal angular process, backwards along the roof to the optic foramen, the outer cut extending from a point just internal to the external angular process, also backwards to the optic foramen. In making these cuts care must be taken to avoid injuring in front on the inner side the pulley and tendon of the superior oblique muscle, on the outer side the lachrymal gland with its vessels and nerves, and posteriorly the optic nerve and ophthalmic artery passing through the optic hole. Having removed the bony part of the roof the periosteum is exposed, and must be examined before proceeding farther.

The *periosteum* of the orbit appears to be a continuation of the dura mater; it passes in through the optic hole, and through the sphenoidal fissure. Entering the optic hole it divides into two portions, one forming a tubular sheath for the optic nerve, and becoming continuous with the sclerotica, the other forming the proper periosteum. Where it enters the sphenoidal fissure it also forms a sheath for the vessels and nerves which pass through that opening. At the anterior margin of the orbit this fibrous membrane divides into two portions, one becoming continuous with the palpebral ligament or fascia, the other with the periosteum of the forehead.

The periosteum may now be removed, and the following parts are seen immediately beneath it: in the middle line the frontal branch of the ophthalmic division of the fifth nerve, on the outer side the lachrymal branch of the same nerve, and on the inner side is the fourth nerve. Immediately under the fourth nerve is the superior oblique muscle; beneath the frontal nerve are the levator palpebræ and superior rectus, and below the lachrymal nerve is the external rectus muscle; beneath the external angular process is the lachrymal gland. Some branches of the ophthalmic artery are seen in this part of the orbit. A considerable quantity of soft fat exists in the orbit, filling up the intervals between the muscles and other parts; some of this must be removed before a clear view can be obtained of the parts which we have enumerated as being visible in this stage of the dissection.

The *lachrymal gland* is contained in a depression on the roof of the orbit, beneath the external angular process of the frontal bone. It is generally about as large as a filbert, of an irregular ovoid form, with its long diameter placed transversely. Its upper surface is convex, and connected by means of fibrous processes to the periosteum; its under surface is concave, and is in relation with the external rectus muscle and the eye-ball. The excretory ducts of this gland, from ten to twelve in number, run parallel to each other, and open by as many orifices beneath the upper lid, about a line from the tarsal cartilage.

The *fourth nerve* enters the orbit by passing through the inner part of the sphenoidal fissure. At this point it is above the other nerves, which pass through the same opening. It then passes forwards and inwards immediately under the periosteum, crossing over the origin of the levator palpebræ and superior rectus muscles, and it is distributed to the orbital surface of the superior oblique muscle.

The *frontal nerve*, a branch of the ophthalmic division of the fifth, enters the orbit with the fourth nerve, but a little below it and on its outer side. It passes forwards between the periosteum and the levator palpebræ, and soon divides into two branches, *internal* and *external frontal*, or *supra-trochlear*, and *supra-orbital*. The supra-orbital is the larger branch; it passes out through the supra-orbital notch or foramen, and divides into ascending *frontal* branches, usually two in number, which are distributed to the skin of the forehead, and descending *palpebral* filaments, which are very numerous and are distributed in the substance of the upper eyelid. The supra-trochlear nerve passes out of the orbit between the supra-orbital notch and the pulley of the superior oblique; it gives off ascending frontal filaments to the skin of the forehead, and descending palpebral and nasal filaments to the upper eyelid and dorsum of the nose.

The *lachrymal* nerve is the smallest of the three divisions of the ophthalmic; it enters the orbit through the sphenoidal fissure external and inferior to the frontal nerve; in its passage through the sphenoidal fissure it is invested in a sheath of dura mater. It runs along the superior border of the external rectus muscle, immediately under the periosteum; it passes through the lachrymal gland, sending numerous filaments to it, and terminates by sending palpebral filaments to the upper lid, one of which passes on and is distributed to the skin of the anterior temporal region. In its course it gives off a *malar* branch, which passes through a canal in the malar bone and is distributed to the skin on the cheek; it also sends down one or two filaments which anastomose with the superior maxillary branch of the fifth nerve.*

We may now examine the three muscles which are placed most superficially in the upper part of the orbit, and which are visible in this stage of the dissection, viz. the levator palpebræ, the superior rectus, and the superior oblique.

The *levator palpebræ superioris* arises tendinous from the inferior surface of the lesser wing of the sphenoid bone above the optic foramen, also from the fibrous sheath of the optic nerve; it passes forwards, and upwards, becoming broader and thinner towards the anterior part of the orbit, where it suddenly curves downwards and ends in a broad thin aponeurosis, which is inserted into the upper border of the tarsal cartilage, behind the palpebral ligament. This muscle is of a triangular form, the apex being posterior; it is crossed by the fourth and frontal nerves, the latter passing forward above and parallel to it, and separating it from the periosteum; it covers the superior rectus and eyeball.

In order to expose the superior rectus, cut through and turn aside the levator palpebræ; in doing so a small branch of the third nerve is seen to enter its inferior surface.

The *rectus superior* arises from the upper part of the fibrous sheath of the optic nerve, and from the outer and upper part of the margin of the optic foramen; the fleshy fibres from this point of origin pass forwards and outwards in the direction of the axis of the orbit; the muscle becomes broader and thinner anteriorly, and ends in a broad aponeurotic expansion, which is inserted into the upper aspect of the sclerotic, a little behind the margin of the cornea. A small synovial bursa is said to exist between the sclerotic and the tendon at its insertion. This muscle is covered above by the levator palpebræ, and by the nerves which cross the levator palpebræ; below it is in relation with the nasal,

* For a more minute account of the distribution of these branches of the fifth nerve, see article FIFTH NERVE.

the third, and the optic nerves, with the ophthalmic artery and the eye-ball.

The *obliquus superior* is a long and slender muscle, which is sometimes called the *trochlearis* muscle from the fact of it being reflected through a trochlea or pulley. It arises from the fibrous sheath of the optic nerve, and from the inner part of the optic foramen between the superior and internal recti muscles; it passes forwards along the internal superior angle of the orbit, in the form of a rounded fleshy belly, to which succeeds a rounded tendon, which after passing through the pulley beneath the internal angular process is directed backwards, outwards, and downwards, passing beneath the superior rectus muscle to be inserted by a thin aponeurosis into the sclerotic coat between the superior and external rectus, rather behind the anterior half of the globe. This pulley or trochlea, through which passes the tendon of the superior oblique, is a small cartiliginous ring, inserted by means of fibrous tissue into a depression beneath the internal angular process; it is lined by a synovial membrane. The orbital surface of the superior oblique is in contact with the periosteum; the fourth nerve passes into this surface about its centre; the relations of its ocular surface are the same as those of the superior rectus.

The superior rectus and superior oblique muscles may now be cut through and turned aside, and after removing carefully some fat and cellular tissue the following parts are brought into view:—the internal and external recti muscles, the optic, the third, and the nasal branch of the ophthalmic nerves, the lenticular ganglion between the optic nerve and external rectus muscle, and the ophthalmic artery and vein.

The *third nerve* before entering the orbit divides into two portions; a superior smaller, and an inferior larger; it enters the orbit through the sphenoidal fissure between the two heads of the external rectus muscle; the inferior division then passes beneath the globe of the eye and must be examined in a subsequent stage of the dissection. The superior division is now visible; it passes to the under surface of the superior rectus muscle, to which it sends numerous filaments; some filaments also pass on the inner side of the superior rectus and enter the deep surface of the levator palpebræ superioris; these are the only muscles supplied by this division of the third nerve.

The *nasal nerve* is in size the second branch of the first division of the fifth. It enters the orbit through the sphenoidal fissure, passing between the two heads of the external rectus muscle, in company with the third and sixth nerves, being external to the former, and between its two divisions, and internal and somewhat superior to the latter. Having entered the orbit, it passes forwards and inwards towards the internal wall, crossing over the optic nerve between it and the superior rectus muscle; it has also above it the levator palpebræ and superior oblique muscles, and the superior division of the third nerve; it passes out of the orbit through the anterior internal orbital hole in company with the anterior ethmoidal artery. Within the orbit it sends off *lenticular*, *ciliary*, and *infra-trochlear* branches. The lenticular branch is given off on the outer side of the optic nerve; it anastomoses with the superior division of the third nerve, and joins the posterior superior angle of the lenticular ganglion. The ciliary branches are two or three in number; given off above the optic nerve, they pass forwards and pierce the posterior part of the sclerotic. The infra-trochlear branch is given off near the inner wall of the orbit; it passes out beneath the pulley of the superior oblique muscle, and sends branches to the superior eyelid, the lachrymal sac, and integuments of the nose; within the orbit there is an anastomosis between this and the supra-trochlear or frontal nerve.

The *lenticular* or *ciliary ganglion* is situated in the posterior and outer part of the orbit between the optic nerve and the external rectus muscle; it is very small, and of a somewhat square form. Its superior posterior angle is joined by the lenticular branch of the nasal nerve, which constitutes the long root of the ganglion; its inferior posterior angle receives a branch from the inferior division of the third nerve; this forms the short root of the ganglion. To its posterior part is also connected one filament from the cavernous plexus, and occasionally one from the spheno-palatine ganglion. From the anterior part of the ganglion a number of delicate ciliary nerves pass off; they are divided into two sets, one set coming from the superior anterior, and the other from the inferior anterior angle of the ganglion; the former are the more numerous; in all they are from twelve to sixteen in number; they pass forwards and pierce the sclerotic near the optic nerve.

The *optic nerve* passes forwards from the optic hole to the inner and back part of the eyeball, which it enters to terminate in the retina. It is invested by a sheath of fibrous membrane, which is continuous behind with the dura mater, and in front with the sclerotic; the outer surface of this sheath posteriorly gives attachment to the recti muscles, which surround the optic nerve as it emerges from the optic hole. The optic nerve is crossed above by the nasal nerve and the ophthalmic artery, below by the branch of the inferior division of the third nerve, which supplies the internal rectus muscle; it is surrounded by numerous delicate ciliary nerves and arteries.

The *ophthalmic artery* passes through the optic hole in company with the optic nerve, and inclosed in a sheath derived from the dura mater. It is very tortuous and twines round the optic nerve, being at first inferior to the nerve, then passing to its outer side, and soon crossing over it to reach its inner side; it then passes across to the inner wall of the orbit, where it breaks up into its terminal branches. The branches of the ophthalmic artery are very numerous; they may be arranged in three sets; the first set arises from the artery as it lies external to the optic nerve; it consists of the lachrymal and the centralis retinæ; the second set comes off from the artery, when it is above the optic nerve; this consists of the supra-orbital, ciliary and muscular; the third is given off when the artery has passed over to the nasal side of the orbit, and consists of the ethmoidal, palpebral, nasal, and frontal arteries.

The *lachrymal artery* is one of the largest branches of the ophthalmic; it arises from the ophthalmic either within the optic hole or immediately after that artery has entered the orbit. It sometimes arises from the middle meningeal artery, and enters the orbit through the sphenoidal foramen. It passes forwards along the outer wall of the orbit between the periosteum and the external rectus muscle; it enters the lachrymal gland, sending numerous branches to it; it then emerges from the gland and supplies the conjunctiva and the upper eyelid. It gives a *malar* branch which passes through the malar bone and anastomoses in the substance of the temporal muscle with the anterior deep temporal artery. The lachrymal artery generally anastomoses with the middle meningeal by a branch sent in through the sphenoidal fissure.

The *central artery of the retina* is a small branch which enters obliquely the optic nerve; it passes forwards in the centre of the nerve, enters the globe of the eye, and expands out into a vascular membrane on the inner surface of the retina. One small branch passes through the vitreous humour and reaches the posterior surface of the capsule of the lens.

The *supra-orbital artery* arises from the ophthalmic while it is above the optic nerve; it is one of the largest branches of the artery: it passes forwards close under the periosteum of the roof, and above the levator palpebræ, in company with the frontal nerve. It escapes from the orbit at the supra-orbital notch, and sends branches on the forehead, some between the skin and muscles, and others between the occipito-frontalis and the periosteum. In the orbit it supplies the levator palpebræ and superior rectus muscles, and sends some branches to the upper lid.

The *ciliary arteries* are very numerous, and are divided into three sets—anterior, middle, and posterior. The anterior ciliary arteries are irregular in number and origin; they usually come off from the muscular branches at the anterior part of the orbit; they perforate the sclerotic about one or two lines behind the cornea: some branches go to the iris and anastomose with the long ciliary arteries; others go to the choroid and anastomose with the short ciliary. The middle or long ciliary arteries are two in number; they accompany the nerves of the same name. They pierce the sclerotic at some distance from the optic nerve, and pass horizontally one on each side between the sclerotic and the choroid. They pass through the ciliary ligament and supply the iris. The posterior or short ciliary arteries are remarkably delicate and tortuous; they are accompanied by the ciliary nerves from the lenticular ganglion. Their origin is somewhat irregular; most of them arise from the ophthalmic artery, but occasionally some from the supra-orbital or from some muscular branches. There are as many as fifteen or twenty of these arteries, which surround the optic nerve in a spiral and tortuous manner; they pierce the sclerotic about two lines anterior to the entrance of the optic nerve, and supply the choroid and ciliary processes. (For the mode of arrangement of these ciliary vessels in the choroid and iris see the article Eye.)

The *muscular branches* are uncertain in number and origin; they usually consist of two sets, a superior and an inferior. The superior set often come from the frontal artery, and supply the levator palpebræ, the superior oblique and the superior rectus muscles. The inferior muscular artery is a regular branch from the ophthalmic; it descends on the inner side of the optic nerve; it first sends a branch to the external rectus and then supplies the inferior and internal recti, and the inferior oblique; some branches pass on to the lower eyelid and the lachrymal sac. These arteries are usually distributed to the ocular surface of the muscles.

The *ethmoidal arteries*, two in number, are given off from the ophthalmic near the inner wall of the orbit. The posterior is usually the larger; it passes through the posterior orbital foramen and enters the skull, where it sends off some anterior meningeal branches, then passes down through the cribriform plate of the ethmoid bone, and is distributed on the mucous membrane of the nose. The anterior ethmoidal passes through the anterior internal orbital foramen with the nasal nerve; it has the same distribution as the posterior branch.

The *palpebral arteries*, two in number, arise near the inner angle of the orbit. The superior arises above the tendon of the orbicularis palpebrarum; it passes outwards and supplies the upper lid, one branch running near the tarsal margin of the lid, while the others are distributed to the muscles and integuments of the middle and upper part of the lid, where they anastomose with the supra-orbital artery. The inferior palpebral artery passes down behind the tendon of the orbicularis, then runs outwards along the lower lid, forming an arch near the free margin of the lid, and is gradually lost near the external canthus. It anastomoses with the angular branch of the facial, with the infra-orbital branch of the internal maxillary, with the transverse facial and temporal arteries. Beneath the internal angular process the ophthalmic artery terminates by dividing into the *nasal* and the *frontal* branches.

The *nasal artery* emerges from the orbit above the tendon of the orbicularis; it anastomoses freely with the angular artery, sends branches to the lachrymal sac, and terminates in a branch which passes down the dorsum of the nose, and communicates at the extremity of the nose with the corresponding artery of the opposite side.

The *frontal artery* passes out of the orbit with the nasal, then turns upwards, and is distributed to the muscles and integuments of the forehead, anastomosing with the supra-orbital and with the arteries of the opposite side.

The *ophthalmic vein* commences at the inner angle of the orbit, where it communicates freely with the angular and frontal veins; it passes backwards in the same direction as the artery, but it is much less tortuous. It receives branches corresponding to those which the artery gives off, and passing between the two heads of the external rectus muscle below the nerves, it terminates in the anterior extremity of the cavernous sinus.

The ophthalmic artery and vein may now be removed; cut through the optic and ciliary nerves and remove some fat and cellular tissue which obscures the remaining muscles and nerves; we now obtain a more clear view of the internal and external recti muscles, and at the same time we expose the sixth nerve and the inferior division of the third, as well as the inferior rectus and the inferior oblique muscles.

The *sixth nerve* passes between the two heads of the external rectus muscle below the third nerve, and above the ophthalmic vein, from which it is separated by a process of dura mater. Having entered the orbit it passes along the inner surface of the external rectus muscle, to which it is distributed by numerous delicate filaments.

The *inferior division of the third nerve* enters the orbit, as we have seen, between the two heads of the rectus muscle, where it lies a little above the sixth nerve; having entered the orbit it passes down towards the floor between the optic and the sixth nerves, and below the level of the latter. It almost immediately divides into three branches: an *internal*, which passes inwards beneath the optic nerve towards the internal rectus muscle, to the ocular surface of which it is distributed; a *middle* branch, which is distributed in the same manner to the ocular surface of the inferior rectus; and an *external*, which passes forwards along the external border of the inferior rectus, and enters the posterior border of the inferior oblique, almost at right angles. The short filament which joins the posterior inferior angle of the lenticular ganglion, forming the short root of the ganglion, is usually given off from the branch which goes to the inferior oblique muscle.

The *external rectus muscle* has two origins, one from a tendon, the tendon or ligament of Zinn, which is common to this muscle with the inferior and internal recti, and which is attached to a little tubercle behind the optic foramen; the other origin of the external rectus is above, from the inner margin of the sphenoidal fissure; this origin is united with the origin of the superior rectus. Between these two origins pass the third, the sixth, and the nasal branch of the fifth nerves, with the ophthalmic vein. From its origin the external rectus passes forwards along the external wall of the orbit; it turns over the globe of the eye, and is inserted by a thin tendinous expansion just behind the margin of the cornea. A small bursa intervenes between the tendon and the sclerotic, as is the case with the tendons of all the recti muscles.

The *internal rectus* arises from the common tendon or ligament of Zinn, and from the fibrous sheath of the optic nerve; it passes forwards along the internal wall of the orbit, turns over the globe of the eye, and is inserted immediately opposite the external rectus, in the same manner as the other recti muscles.

The *inferior rectus muscle* arises from the common tendon, between the internal and external recti; it passes forwards under the globe of the eye and is inserted into the sclerotic in the same manner as the preceding muscles, and immediately opposite the superior rectus. The recti muscles have all the same form, viz. that of a long isosceles triangle, having the base directed forwards, and the apex backwards. They differ in length and thickness; the internal rectus being the shortest and thickest, the external rectus the longest, and the superior rectus the smallest.*

The *inferior oblique muscle* is the only one which does not arise from the apex of the orbit. It arises from the orbital plate of the superior maxillary bone, just within the margin of the orbit, and near the groove for the lachrymal sac. From its origin it passes obliquely outwards, upwards, and backwards beneath the globe of the eye and the inferior rectus, then between the former and the external rectus; it ends in an aponeurotic expansion which is inserted into the sclerotic between the superior and external recti, opposite the insertion of the superior oblique, and rather nearer the optic nerve than the insertion of that muscle. The superior surface of this muscle is in contact with the inferior rectus and the globe of the eye; the inferior touches the floor of the orbit and the external rectus muscle; its borders are anterior and posterior; a branch of the third nerve enters the posterior border.

The *orbital portion* of the *superior maxillary nerve* may now be exposed by cutting through the external rectus muscle, and drawing the eye with its muscles towards the inner part of the orbit. The nerve having crossed the spheno-maxillary fossa enters the orbit through the spheno-maxillary fissure; in company with a branch of the internal maxillary artery it passes along the infra-orbital groove, covered by a layer of periosteum; it then passes through the canal and emerges from the infra-orbital foramen. The trunk of the nerve is but little visible on the floor of the orbit. While the superior maxillary nerve is in the foramen rotundum, or during its passage across the fossa, it sends off a *temporo-malar* branch which passes through the spheno-maxillary fissure superior and external to the trunk of the nerve; it passes along the floor of the orbit, beneath the inferior rectus muscle, and about the middle divides into two branches, a *temporal* and a *malar*.

The *temporal branch* goes towards the outer wall of the orbit, passes up between the bone and the external rectus muscle, and joins with a temporal branch from the lachrymal; it then pierces the orbital process of the malar bone and enters the temporal fossa, where it communicates with the anterior deep temporal nerve, sends branches to the temporal muscle, and piercing the fascia is distributed to the skin over the temporal region.

* Cruveilhier. Descriptive Anatomy.

The *malar branch* passes on to the inferior external angle of the orbit, where it sometimes communicates with the lachrymal nerve; it enters one or more canals in the malar bone, and appears on the facial surface, supplying the orbicularis and the integuments, and communicating with the portio dura.

In addition to the structures ordinarily described as existing within the orbit, Mr. O'Ferrall has described * a fibrous structure, to which he gives the name of "tunica vaginalis," and which invests the globe of the eye, separating it from the muscles and fat of the orbit. In order to expose the outer surface of this structure, a vertical incision must be made through the integument of the upper lid; after removing carefully the orbicularis and a fascia, between the two layers of which the tendon of the levator palpebræ is inserted, the part next in order is the tarsal cartilage. Tracing this upwards and backwards its thin margin is found to be continuous with a fibrous lamina, which passes back into the orbit and separates the globe of the eye from the superior rectus muscle, but presenting a well-defined opening, through which the tendon of the muscle passes as over a pulley, to be inserted into the sclerotic coat. In order to examine the ocular surface of this membrane, Mr. O'Ferrall advises a vertical division of both palpebræ, then an incision through the conjunctiva at the angle of reflection from the eyelid to the ball of the eye.

The incision being made and the edges of the divided membrane separated, we expose the ocular surface of "a distinct tunic of a yellowish white colour and fibrous consistence, continuous in front with the posterior margin of the tarsal cartilage, and extending backwards to the bottom or apex of the orbit, where its consistence becomes less strongly marked." This ocular surface is smooth where the eye glides over it in its movements, and is connected to the surface of the globe by fine cellular tissue. The muscular substance of the recti muscles is on the outside of this tunic and invisible through it; but about half an inch posterior to its anterior margin are six well-defined openings through which the tendons of the muscles emerge in passing to their insertion in the sclerotic coat. Mr. O'Ferrall was induced to look for this structure in consequence of meeting with cases in which the globe of the eye and the conjunctiva were protruded in a manner not satisfactorily explained by reference to any previously described structure. He believes these to have been cases of inflammation of this tunic, with effusion between its deep surface and the globe of the eye.

Mr. O'Ferrall believes that "the uses of this tunic are to present a smooth surface, facilitating the movements of the eye; and by its density and tension, to protect it from the pressure incidental to the swelling of its muscles during their action. That the openings in this tunic perform the office of pulleys, giving a proper direction to the force exerted by the muscles,—securing the motions of rotation, and opposing those of retraction, which would otherwise predominate."

Action of the muscles.—The action of the *levator palpebræ* muscle is to raise the upper lid, and thus to expose the anterior part of the eye-ball. In this action it is an associate of the frontal portion of the occipito-frontalis, and an antagonist of the orbicularis palpebrarum. Sir C. Bell * affirmed that the action of the levator palpebræ is not simply that of raising the upper lid, but that the swelling and tension of the muscle during its action have the effect of pushing forwards the eye-ball, thus causing the lower lid to slide off the convex surface of the eye, and to be depressed whilst the upper lid is elevated. There is no proof of any such action of the levator palpebræ, and it seems improbable that it should exert any such influence, separated as it is from the eye-ball by the superior rectus, by a considerable quantity of fat and by the "tunica vaginalis." The result of paralysis of this muscle is a dropping of the upper lid, to which the term *ptosis* is applied.

It is evident from an examination of the origin, course, and insertion of the *recti* muscles, that each of them acting singly is capable of making the eye-ball revolve in its own direction; the superior rectus directs the cornea upwards; the inferior rectus antagonises the superior and directs the cornea downwards; the external rectus directs it outwards and is antagonised by the internal, which draws the cornea inwards towards the nose. It is also evident that the action of any two contiguous recti muscles will give the cornea a direction intermediate between that which it would assume from the action of each of them singly; the superior and internal recti acting together will direct the cornea upwards and inwards, while the inferior and external will direct it downwards and outwards; so that the cornea may be made to assume any intermediate position by the action of the recti muscles alone.

The successive action of all the recti muscles would produce a movement of the eyeball analogous to *circumduction* of a limb; and as the circumduction of a limb is a movement altogether distinct from rotation, so is this circumduction of the eye-ball entirely distinct from any rotation upon its antero-posterior axis. In circumduction the centre of the cornea describes a circle, whereas in rotation this point remains fixed, forming the anterior extremity of an imaginary axis, round which the circumference of the cornea revolves. It is of much importance to have a definite notion of each of these movements, as we shall thus avoid one source of confusion in considering the action of the straight and oblique muscles of the eye. Having thus defined rotation, no argument is necessary to prove that the recti muscles are incapable of producing such a movement; a glance at their direction

* Dublin Journal of Medical Science, July, 1841.

* The Nervous System of the Human Body, by Sir C. Bell.

and their position with regard to the eye-ball will at once determine this point. If then any such movement occurs, other muscles must be provided in order to effect it.

We now proceed to consider the action of the *oblique* muscles.

It may be well to remind the reader that, in all the vertebrate animals, these muscles have essentially the same direction and relations; the only difference being that in fishes, reptiles, and birds, the superior oblique arises from the anterior part of the orbit, whence it passes backwards and outwards to its insertion; whereas, in Mammalia, it comes from the posterior part of the orbit and passes through a tendinous pulley before taking its course backwards and outwards; the action of the muscle will obviously be the same in both cases. One function which has been assigned to the oblique muscles, is that of antagonising the recti so as to prevent the retraction of the eye-ball within the orbit during the action of the latter muscles. To this conclusion Sir C. Bell asserts there are many objections: two of these objections we subjoin in his own words. "1. In creatures where the eye is socketed in a cup of cartilage and cannot retract, the oblique muscles are nevertheless present. 2. Where a powerful retractor muscle is bestowed in addition to the recti muscles to pull the eye-ball back, the oblique muscles have no additional magnitude given to them to pull the eye-ball forwards." Now we must not suppose that the antagonism exerted by the oblique muscles is such as to oppose the conjoint forcible action, or active contraction, of all the recti muscles, and of a retractor when such a muscle exists. If such were the case, we should certainly find the developement of the oblique muscles in some degree proportioned to that of the muscles they were intended to antagonise, and a cup of cartilage at the back of the eye-ball would apparently supersede the necessity for any antagonism on the part of the oblique muscles; but the kind of antagonism which the oblique muscles probably exert upon the recti is equally necessary whether the eye-ball be encased in cartilage or supplied with a retractor muscle. It is simply the same kind of antagonism which the muscles on the opposite sides of the face exert upon each other. Paralysis of the portio dura on one side is attended with a traction of the features to the opposite side; this results from the ordinary tonicity or passive contraction of the muscles on the one side, unopposed by the corresponding force on the other; the distortion is generally conspicuous enough when the muscles are at rest, but when they are thrown into active contraction it becomes still more marked, and the movements of the sound side are unsteady and oscillating. During the healthy state then the symmetry of the features is maintained by this antagonism of the muscles on opposite sides of the face. In like manner when the muscles are at rest, the eye-ball is kept delicately balanced between its six muscles; the superior rectus opposes the inferior, and the external opposes the internal, while the obliqui are opposed to each other, and the recti conjointly are antagonised in their retracting tendency by the opposite force of the obliqui. This is the condition during a state of rest, when the contraction of all the muscles is merely that of their ordinary tonicity or passive contraction. Now, suppose one straight muscle to be thrown into a state of voluntary active contraction; immediately the cornea is directed towards that muscle, the antagonism of the other five muscles serving the important purpose of preventing any irregular oscillatory movement of the eye-ball; when the contraction of that muscle ceases, the eye is at once restored to its original position. One of the uses of the oblique muscles then is by their antagonism of the recti to assist in preventing any unsteady motion of the eye-ball. This, however, is by no means the only or the chief use of the oblique muscles, and the question arises, what movements of the eye-ball are effected by the contraction of these muscles? Upon this subject the most contradictory statements have been made; on the one hand Sœmmering, Cloquet, and Harrison assert, that the superior oblique directs the pupil downwards and inwards, the inferior oblique moves it upwards and outwards; on the other hand, according to Müller, Monro, and Sir C. Bell, the superior oblique directs the pupil downwards and outwards, the inferior oblique upwards and inwards. All these anatomists agree in supposing that the oblique muscles effect what we have called circumduction of the eye-ball, but their disagreement as to the direction in which circumduction occurs under the influence of these muscles, is of itself an argument against the probability of any such movement being produced by them. We have before stated that the recti muscles are of themselves capable of circumducting the eye in all directions: this was admitted and proved experimentally by Sir C. Bell. He "cut across the tendon of the superior oblique muscle of the right eye of a monkey. He was very little disturbed by this experiment, and turned round his eyes with his characteristic inquiring looks, as if nothing had happened to affect the eye." In another experiment he "divided the lower oblique muscle of the eye of a monkey. The eye was not, in any sensible manner, affected; the voluntary motions were perfect after the operation." The result of these experiments appeared to Sir C. Bell to confirm the opinion which he entertained that the oblique muscles perform certain involuntary movements, such as the forcible elevation of the cornea under the upper lid when the eye is irritated, and the rolling of the cornea under the lid when the eye is closed. He appears anxious to prove that the fourth nerve presides over the upward movement of the eye-ball which he says occurs during sneezing and certain other respiratory movements; but as he has previously stated that the superior oblique to which the fourth nerve is distributed turns the eye *downwards* and outwards, in order to reconcile the two views he says, "if we suppose that the influence of the fourth nerve is, on certain occasions, to cause a relaxation of the muscle to which it goes, the eye-ball must be then rolled upwards."*

Sir C. Bell adduces no proof that the involuntary movements which he mentions are performed by the oblique muscles; on the contrary they may all be effected by the straight muscles. The fact that these movements are involuntary is no argument against their being produced by muscles, which under ordinary circumstances are strictly voluntary. Thus, Sir C. Bell says, when the eye is exposed and irritated, the cornea is directed upwards to a greater extent than can be done by a voluntary effort. This probably is the case, but we need not have recourse to the oblique muscles in order to explain it. Under the influence of the irritation applied to the eye the superior rectus contracts violently in order to elevate the cornea beneath the upper lid, and thus to remove it from danger; precisely in the same manner under the irritating influence of strumous ophthalmia the orbicularis muscle contracts with a spasmodic force much exceeding that of any voluntary contraction of that muscle. Both oblique muscles have the striated structure of voluntary muscles, and the inferior oblique receives a branch from the third nerve, all the other muscles supplied by which are known to be voluntary in their action. We may, therefore, dismiss the idea that the oblique muscles are specially concerned in producing the involuntary movements of the eye.

Further, it is our firm conviction that the oblique muscles are in no way concerned in circumduction of the eye-ball; that they neither abduct nor adduct, neither raise nor depress the cornea, nor do they produce any of the intermediate movements. The following are the circumstances which appear to us to favour this conviction. 1st. Both oblique muscles pass outwards almost at right angles with the recti muscles, and are inserted close upon a line intermediate between the anterior and posterior half of the eye-ball: this direction and insertion are evidently most unfavourable for the production of any of the above-mentioned movements. 2d. Those who assert that the oblique muscles have the power of circumducting the eye make the most contradictory statements as to the direction which the eye assumes under their influence. These opposite statements are sufficiently accounted for when we consider that they are founded on the results of traction on the oblique muscles after death, when the fat and other parts in the orbit have become firm and unyielding, and the steadying influence arising from the antagonism of the other muscles has ceased. 3d. The recti muscles are of themselves capable of circumducting the cornea in all directions; this is evident from their direction and insertion, and was proved by Sir C. Bell's experiments above-mentioned. 4th. There is an important movement of the eye-ball which can be effected by no other than the oblique muscles, and for the production of which in all probability these muscles are provided: the movement to which we refer is rotation of the eye upon its antero-posterior axis.

The true use of these muscles we believe to have been pointed out by John Hunter in a paper on the use of the oblique muscles, in his "*Observations on certain Parts of the Animal Economy*." He first explains that for perfect vision it is essential that when we are examining an object, any motion of the object or of our own bodies should be so counteracted by the movements of the eye-ball that the image of the object may be kept on the same point of the retina, and not be allowed to move over its surface. We have a familiar illustration of this when we keep our eyes motionless and fixed on the ground, while moving rapidly in a carriage; the surface of the road appears confused and the stones arranged in lines, as their images pass rapidly over the retina: it is only when we allow the eye to follow these objects that we have a distinct perception of any of them. Hunter then goes on to explain the use of the oblique muscles. "To prevent any progressive motion of the object over the retina of the eye, either from the motion of the object itself, or of the head in some motions of that part, the straight muscles are provided, as has been explained; but the effects which would arise from some other motion of the head, as from shoulder to shoulder,* cannot be corrected by the action of the straight muscles, therefore the oblique muscles are provided. Thus, when we look at an object and at the same time move our head to either shoulder, it is moving in the arch of a circle whose centre is the neck, and, of course, the eyes would have the same quantity of motion on this axis if the oblique muscles did not fix them upon the object. When the head is moved towards the right shoulder the superior oblique muscle of the right side acts, and keeps the right eye fixed on the object, and a similar effect is produced upon the left eye by the action of its inferior oblique muscle. When the head moves in a contrary direction, the other oblique muscles produce the same effect."

If we again consider the direction and insertion of the oblique muscles, it is evident that they are intended for the office which Hunter has assigned them. Passing outwards, one above, the other below, in a direction almost at right angles with the antero-posterior axis of the eye-ball to their insertion near its middle, their action must obviously be to rotate the eye upon that axis. The reason of their obliquity probably is that their direction backwards as well as outwards, by enabling them to antagonise the straight muscles, more certainly se-

* See Sir C. Bell on the Nervous System, p. 177. This supposition appears to us as unphilosophical as the old theory of Phlogiston, which, in order to explain the fact of a body becoming heavier when deprived of this imaginary agent, attributed to phlogiston a property of lightness.

* The motion here meant is that which is effected by flexion of the neck laterally, so as to approximate the ear to the shoulder, not that movement which takes place between the first and second cervical vertebræ.

cures the delicate suspension of the eye-ball when the muscles are at rest, and a steady movement of it when any of them are thrown into action. We have the following experimental evidence to offer in support of the statement which Hunter has made. A dog was killed by the injection of air into a vein, and immediately the inferior oblique muscle was exposed by dissecting off the conjunctiva, without in any way interfering with the surrounding parts; by means of two fine wires a slight electric current was then directed through the muscle. The effect was a rapid rotation of the eye upon its antero-posterior axis, so that a piece of paper placed at the outer margin of the cornea passed downwards and then inwards towards the nose. The superior oblique was then exposed at the back of the orbit, and was treated in the same manner. The rotatory movement produced was precisely the reverse of the former; the paper at the outer margin of the cornea passed upwards, and then inwards towards the nose. In the case of the superior oblique the movement was less extensive, the irritability of the muscle being less, perhaps from the delay in exposing it, and from some slight injury inflicted on it in so doing. There could be no doubt as to the direction of the movement in both cases; there was not the slightest appearance of elevation, depression, abduction, or adduction of the cornea. This experiment was witnessed by Dr. Todd and Mr. Bowman. The experiment was subsequently repeated on another dog with precisely the same result. The superior oblique in the second experiment did not contract so vigorously as the inferior, but the movement it produced was the same as in the first experiment; and when gentle traction was made in the posterior part of the muscle, the rotation of the eye was very decided, and in a direction the reverse of that in which it rotated under the influence of the inferior oblique; again there was not the slightest movement of circumduction. There can be no doubt that the function of these muscles is the same in all animals in which they exist; and any experiments to determine their use must be more satisfactory when performed on animals immediately after death than in the human subject at a considerable period after death, when the fat and muscles have become equally firm and unyielding. Under such circumstances it is evident that the results of traction upon the muscles cannot be relied upon as accurate. It is remarkable that this rotation of the eye should have excited so little attention; since, if we only recognise the existence of such a movement, the use and necessity of the oblique muscles must be acknowledged, it being evident, as we have previously stated, that the straight muscles are incapable of effecting it.

Consensual movements of the two eyes.— Upon this subject we subjoin the following extract from Müller:*—" There is an innate tendency and irresistible impulse in the corresponding branches of the third nerve to associate action; while in the sixth nerve, not only is this tendency absent, but the strong action of one of these nerves is incompatible with the action of the other. These innate tendencies in the third and sixth nerves are extremely important for the function of vision, for if, in place of the sixth nerves, the external recti muscles had received each a branch of the third nerve, it would have been impossible to make one of these muscles act without the other; one eye, for example, could not have been directed inwards while the other was directed outwards, so as to preserve the parallelism or convergence of their axes, but they would necessarily have diverged when one rectus externus had been made to act voluntarily. To render possible the motion of one eye inwards while the other is directed outwards, the external straight muscles have received nerves which have no tendency to consensual action. In consequence, however, of the tendency in the two internal straight muscles to associate action, it is necessary, where one eye is directed inwards and the other outwards, that the contraction of the rectus externus of the latter should be so strong as to overcome the associate action of the rectus internus of the same eye; and in the effort to direct one eye completely outwards we actually feel this stronger contraction of the external rectus."

It is certainly contrary to our general notions of the skill and economy of nature to suppose that she would so clumsily construct and endow the muscles and nerves of the eye, that in order to direct one eye outwards the external rectus muscle must struggle with and overcome the internal rectus of the same eye in consequence of this " irresistible impulse in the corresponding branches of the third nerve to associate action." Doubtless the generality of those who have no theory to support will acknowledge that in directing the eye outwards they are unconscious of any such struggle between opposing muscles as is here supposed, and that abduction of the eye is attended with as little effort as either its elevation or depression. There is then no such irresistible tendency to associate action between the branches of the third nerve supplied to the internal recti muscles. Both internal recti muscles may be made to act at the same time, and thus to produce a convergence of the optic axes; and this being an unnatural position of the eyes is attended with a considerable and a painful effort, each internal rectus having to overcome the external rectus of the same eye, which has a tendency to consentaneous action with the external rectus of the other eye. That the external rectus must have the advantage in any struggle between it and the internal rectus is evident from the greater thickness and consequent strength of the former muscle. The only muscles supplied by the third nerve in which this tendency to consentaneous action is irresistible, are the superior and inferior recti of both eyes; we cannot possibly raise one eye without at the same time raising the other, nor can we depress one eye without a corresponding movement of the other. Then, as we have seen, there is no tendency to

* Physiology, by Dr. Baly, p. 99.

consentaneous action between the branches of the third nerve supplied to the internal recti muscles, and it is only by a considerable effort that they can be made to act together; whilst the branches of the same nerve supplied to the levatores palpebrarum, which for the most part act consentaneously, may by a very slight effort of the will be made to act separately; but few persons experience any difficulty in opening one eye while the other is closed. Again, the tendency to consentaneous action between the internal rectus supplied by the third nerve and the external rectus supplied by the sixth nerve, as well as between the inferior oblique supplied by the third nerve and the superior oblique by the fourth, is as irresistible as that between the superior and inferior recti of the two eyes. We see then that all the muscles supplied by corresponding branches of the third nerve have not this tendency to consensual action, and two muscles supplied by the third nerve act consentaneously with two other muscles supplied by the fourth and the sixth nerves respectively.

For the maintenance of the parallelism between the axes of the two eyes, it is evidently necessary there should be a consentaneous action of the superior recti as well as of the inferior recti; it is also necessary that the internal rectus and the inferior oblique of one eye should act with the external rectus and the superior oblique of the other; but it is by no means evident why it is necessary, in order to effect this, that the external rectus and the superior oblique should each have a nerve specially provided for them. We must not suppose we are explaining the necessity for this arrangement by asserting that "if in place of the sixth nerves, the external recti muscles had received each a branch of the third nerve, it would have been impossible to make one of these muscles act without the other," because, as we have seen, there is no such irresistible innate tendency in *all* the corresponding branches of the third nerve to consentaneous action. Assuming that the use of the oblique muscles is such as we have mentioned, it is certainly curious to observe that when corresponding muscles of the two eyes are intended to act together, as the superior rectus of one eye with the superior rectus of the other, and the same with the inferior recti, both muscles are supplied by the third nerve, but the external rectus which acts consentaneously with the internal rectus of the opposite eye has a separate nerve, the sixth, and the superior oblique, which acts with the inferior of the opposite eye, has the fourth nerve entirely devoted to it.

There is one other phenomenon to which we may briefly allude, namely, the *adaptation of the eye to distances*. This will be found fully discussed under the article VISION; but it deserves a passing notice in this place, since one hypothesis by which an attempt has been made to explain it is that a change is effected in the form of the eye by the action of its external muscles, some writers attributing the influence in question to the recti muscles, and others to the obliqui. It seems by no means improbable that the action of both sets of muscles at the same time might have the effect of increasing the antero-posterior diameter of the eye-ball, and thereby of adapting it for vision at small distances. The following experiment seems to favour the notion that there is some muscular action in the adaptation of the eye to vision at very small distances.

Place a printed page closer to the eyes than the natural focal distance, and merely look upon the letters without making any effort to read them; they appear confused and indistinct; then by a considerable voluntary effort which cannot be long sustained, and which is attended with some pain, we may so adjust the eyes that the letters appear perfectly distinct and legible. This subject is attended with great difficulties, indeed it is scarcely possible to determine the precise mode in which adaptation is effected; the hypothesis we have now mentioned appears at least as probable as any other; it is, however, open to objections. The state of adaptation of the eye is often entirely changed in a very short time by the local action of narcotics, which at the same time dilate the pupil, and this change is effected without any apparent influence over the voluntary contractions of the muscles. Most observers state that the eye is rendered long-sighted (presbyopic), while others have experienced an opposite result. Müller has recorded the results of the application of belladonna to his own eye; the general effect was to render the eye presbyopic, but the capability of adaptation was not destroyed by it. When the solution of belladonna was applied to one eye both eyes were affected, but in different degrees, so that both eyes could not be adapted to distinct vision of the same object at the same moment. These effects were attended with great dilatation of the pupil, and inasmuch as they were probably in some way dependent on this, they are opposed to the hypothesis that adaptation is effected by any action of the external muscles.

(G. Johnson.)

ORGANIC ANALYSIS.—Under the term organic analysis are included the various methods of discovering the constituent parts of substances, formed either directly by the vital actions of organized beings, or indirectly by subjecting the products of such actions to the further operation of re-agents. To treat the subject in its full extent would, however, be foreign to the purpose of the present article, in which I shall confine myself to the analysis of the products of animal life, and particularly of those combinations liable to be met with in the human frame.

In this analysis two distinct objects present themselves: the first consists in the determination of the proximate principles which enter into the constitution of the substance to be analyzed, and the second in the discovery of the elementary composition of the different proximate principles.

I shall therefore in the first place describe the various means by which we recognize the occurrence of the more important proximate animal principles, and determine as far as we are able the quantities in which they may be present: this portion of the subject I shall conclude with a brief sketch of the general method of analysing the principal secretions in the healthy and more ordinary morbid conditions,—for more ample details I must refer to the articles specially devoted to the history of each secretion. I shall then, in the second place, proceed with an outline of the processes best adapted to the ultimate analysis of organic bodies in general.

To the pathologist the first of these objects is the most important, and it is he alone who possesses the extensive facilities requisite for investigating the different varieties exhibited by the secretions in disease, whether these varieties present themselves in the undue prevalence of one or more of the proximate principles, the undue deficiency of any of them, or the unusual occurrence of any of them among the secretions, or in the tissue of particular organs. The value of such information to the enlightened practitioner is sufficiently evident, for an accurate and ready mode of appreciating these changes not only affords him some of the most unerring indications of the nature and progress of disease, but enables him likewise to appreciate the effects and influence of the remedial measures that he may think it needful to adopt. To the chemist, on the other hand, belongs more appropriately the task of determining what ought to be considered as really proximate principles, of insulating them in a pure state, and finally of ascertaining their elementary composition by ultimate analysis.

In every case, before proceeding to analysis, it is desirable, nay, in the present state of science almost necessary, to subject the material to a careful microscopic examination; for although this does not of itself suffice to determine the chemical nature of the substances with which we have to deal, it yet furnishes us with the most important preliminary information we can acquire, and is frequently, owing to their close chemical relationship, the only means of ascertaining what is the form of the azotised constituents of the body with which we have to do. In truth, unless a chemist be likewise in some degree acquainted with the resources placed at his disposal by the microscope, he is but half fitted for the task of organic analysis.

For the necessary information respecting the minute structure of the different products of animal organization, I must again refer to the various articles on the subject in different parts of this work. (See Blood, Chyle, Milk, Mucus, Pus, Saliva, Urine, &c.)

I.—Proximate analysis.

As the limits of this article preclude the possibility of my entering into detail upon the ordinary operations of analysis, a task happily rendered unnecessary by the excellent manuals we possess on the subject, I shall limit myself to a few remarks on processes connected more immediately with organic analysis.

It is needless here to insist upon the importance of scrupulous attention to the purity of the re-agents employed, as it is a precaution sufficiently obvious. These re-agents are few in number: sulphuric, nitric, hydrochloric muriatic), and acetic acids, solutions of potash, ammonia, and carbonate of ammonia, alcohol, and ether, constitute the most important; if to these we add solutions of

Chloride barium,	Acetate lead,
Nitrate silver,	Subacetate lead,
Oxalate ammonia,	Sulphate copper,
Phosphate soda,	Sesquichloride iron,
Ferrocyanide potassium,	Bichloride platinum,
Alum,	Tincture galls,
Lime water,	Hydrosulphuret ammonia,

with a blowpipe, platinum foil, spirit-lamp, forceps, test-tubes and a stand for them, a few watch-glasses, evaporating dishes and Florence flasks, a retort stand, funnels of different sizes, filtering paper and some lipped glasses, with pieces of glass rod and strips of window glass, we shall be tolerably well prepared for the operations of proximate analysis. Of course distilled water must always be employed in analytical enquiries.

For proximate analysis scales weighing 2000 grains and turning with $\frac{1}{10}$th of a grain, when fully loaded, will be sufficient; but for ultimate analysis they should be sensible to $\frac{1}{100}$th of a grain when each pan carries 1000 grains.

When the weight of a dry residue is to be ascertained, the object is attained with most accuracy by first counterpoising the vessel when empty, and then determining the increase of weight after the desiccation is completed.

The *desiccation* of all organic substances is best performed, where practicable, in the exhausted receiver of an air-pump, over sulphuric acid, by Leslie's process: a flat dish of oil of vitriol is placed on the plate of the pump, and the substance to be dried supported above it in a basin by a triangular framework of wire; the air is exhausted, and care taken to maintain a good vacuum; the residue thus procured is always much purer and whiter than that furnished by any other means, but it is a tedious and circuitous process, and requires ten days or a fortnight for its completion. Upon this account, and for other reasons, this method cannot generally be adopted. The plan which, next to it, presents the fewest objections, consists in evaporating by a steam or water heat, so that the temperature can never exceed 212° Fahr. Various methods may be resorted to for effecting this object; by placing one basin within another containing water, an extemporaneous bath is procured; but the end is more conveniently attained by the employment of a shallow box of copper, zinc, or tin plate, in the top of which are half-a-dozen circular apertures of different sizes with projecting vertical rims, upon which lids may be fitted when not in use; any vessel to be heated is placed over one of these apertures, and the temperature maintained by oil, gas, or sand heat.

Perfect desiccation is essential to accuracy, and from the destructible nature of some organic compounds, especially under the combined influences of atmospheric oxygen and an elevated temperature, it is dangerous to effect it by heat and difficult by any other means. In some delicate experiments the following plan, which combines the application of moderate heat with Leslie's method, already described, may be advantageously employed, though the manipulation is rather complicated and troublesome. In a counterpoised retort which will sustain exhaustion, a given weight of the substance to be dried is placed and connected with a tubulated receiver containing oil of vitriol, by a sound cork secured on the exterior with several folds of bladder, well soaked before applying it. Through the tubulure of the receiver passes a small glass tube. This junction likewise is rendered air-tight, with a cork and bladder. The tube, about an inch from the tubulure, is, previous to its insertion, drawn out and narrowed to a capillary bore, so that at pleasure it may be easily drawn off and sealed by a jet of flame from the blowpipe. Matters being thus arranged, the tube from the receiver is united by a connecter of caoutchouc with another tube, and this again with the air-pump, and exhaustion is performed. When a sufficient vacuum has been produced, the whole is allowed to stand for an hour. If, at the end of that time, the mercury in the gauge retain its level, the apparatus is air-tight and may be detached from the pump by sealing the tube proceeding from the receiver in its capillary portion. We may now apply a gentle heat to the bulb of the retort by means of a water bath, or otherwise, and can cool the receiver. Great caution is of course requisite in handling the exhausted vessels, as the slightest abrasion of the surface might cause fracture.

In some cases, as in drying blood, a temperature of 230° may be safely used by employing a boiling solution of Rochelle salt as the exterior bath; and in the analysis of the bile a heat of even 260° is recommended by Berzelius. Where sugar or urea is present, even a heat of 200° is injurious, and must therefore be avoided. The operation we are now considering appears one of the simplest that the chemist can have to perform, but I have been induced to dwell the longer upon it as it is one from which, without great care, more mistakes arise than from any other, owing to the pertinacity with which water adheres to most organic substances. The temperature attainable in an open basin over the water bath is much lower than we should, *à priori*, have been led to imagine. I found, for example, that the temperature of some wheat flour thus drying in an open basin was only 144° F., whilst the water in the bath continued steadily at 196° F. When the basin was covered with a piece of paper, a temperature of 161° F. was the highest attained, while a thermometer placed in the water of the bath stood at 194° F. With liquids evaporating it rises somewhat higher; when plain water was evaporated it stood at 164°, the water in the bath being 208°; and in the case of a viscid fluid like yeast, it varied between 176° and 180°, while the bath raised a thermometer inserted in it to 210°.

It is therefore desirable to have an apparatus in which we can ensure any given temperature from 212° upwards. For this purpose Liebig has contrived a kind of hot-water oven, consisting of a double box of copper; in the interval between the outer and inner walls, water, saline solutions, or oil, may be poured and heated in the usual way. In one side of this box is a door which may be closed when necessary. The interior chamber and its contents can thus be maintained with certainty at the same temperature as that of the fluid around them. The best plan of proceeding consists in evaporating liquids to apparent dryness upon the open water bath; and afterwards subjecting the solid residue, when a temperature of 212° is not injurious, to complete desiccation in Liebig's oven. So long as the material under examination loses weight, the application of heat must be continued.

Capsules of Wedgewood ware or Berlin porcelain are indispensable, and one or two small platinum dishes will be found most valuable, especially in the evaporation of albuminous fluids, as the dry residue adheres so strongly to the glaze of earthen vessels that a portion of the basin is invariably removed along with the animal matter, which thus acquires an undue increase of weight, and the surface of the vessel becomes rough and unfit for use from the difficulty of cleaning it. The Berlin porcelain crucibles are excellent vessels for evaporation, as, being fitted with covers, the dry residue may be preserved from absorbing moisture during the operation of weighing, by exposure to air. It may be worthy of notice that adhering organic substances may be removed from the surface of vessels in which they have been kept, by digestion in concentrated nitric or sulphuric acid, or else by strong solution of potash.

Incineration of the dry residue is accomplished by taking a counterpoised porcelain or platinum capsule with a determinate quantity, say 10 or 12 grains, of the material to be burned, and heating it over a circular wicked spirit-lamp until the ash completely loses its black colour. The capsule should at first be covered to prevent loss by dispersion on the first application of heat; when visible fumes cease to arise, the cover may be removed to allow freer access of air; as, however, the temperature rises higher when the vessel is covered, it will often be found advantageous to leave it loosely covered and maintain a steady heat; sufficient air finds access to consume the carbonaceous matter. Sometimes the ash may be stirred carefully with a platinum wire in order to expose it more fully to the air. When the ash contains alkaline phosphates, the last traces of carbon are burned off with difficulty, as the phosphates fuse and protect the unburned particles from the further action of the air. This inconvenience may be overcome by moistening the residue (after the capsule has been allowed to cool) with a few drops of nitric acid, and again igniting, repeating this manœuvre as often as may be necessary. A new difficulty, however, arises when chlorides are present, as is almost always the case; for at a high temperature these salts are decomposed by nitric acid, and the residue therefore appears to contain less chlorine than is really combined with it.

As the alkaline chlorides are, moreover, not completely fixed at a red heat, some loss is not unfrequently sustained by a long continued ignition. We may dispense with the employment of nitric acid and avoid loss from volatilization by shortening the period during which a high temperature is kept up, and simply charring the mass at a low red heat so as to destroy all organic matter; the black residuum is then digested in water, by which the alkaline salts dissolve, and after well washing, a little weak nitric acid is employed to remove the earthy compounds: charcoal alone remains undissolved. By evaporation of the solutions the amount of saline matter is ascertained.

Filtration may be performed on good white unsized blotting paper cut of a size to drop completely within the funnel; before pouring in the fluid to be cleared, the filter should be moistened, if the solution be aqueous, with water; if alcoholic or ethereal, with a few drops of alcohol or ether, as the case may be. In order to ascertain the quantity of dry residue, the preferable plan is to employ two filters previously counterpoised one against the other, and to insert one into the other; the excess of weight the inner filter shews when the filtration is complete, after both have been carefully dried on the water-bath, will furnish the quantity of solid matter. To render the filtration more rapid, the apex of the outer filter may be cut off so as to leave only one thickness of paper at the point. Occasionally we may weigh the filter itself and mark its weight in pencil upon it; the objection to this plan consists in the difficulty of obtaining the paper always at the same point of dryness. It should be first dried at 212°F., placed in a light covered capsule over sulphuric acid, and allowed to cool, then weighed whilst covered from the air. The same care must be observed on again weighing it with the precipitate. Of course in washing an organic precipitate, the same precautions will be required as when proceeding with the analysis of a mineral. The stream of washing liquid should be specially directed to the edges of the filter, which may be known to be sufficiently washed, when by the evaporation of a drop of the liquid which passes through on a slip of glass, no perceptible stain is produced.

Whenever *decantation*, or pouring off from the sediment, can be substituted (as it very frequently may in alcoholic and ethereal digestions) for filtration, it is to be preferred, as some loss is unavoidably occasioned by every filtration; whereas by decantation the precipitate may be dried in the vessel, and if this have been previously counterpoised we can ascertain the weight of adhering matter with great exactness. By this method the precipitate may be as perfectly washed as when filtration is adopted; the fluid may be poured off very close to the solid matter, which may again be diffused through a fresh portion of washing fluid, again allowed to subside, and the washing repeated as often as may be necessary. In pouring a fluid from one vessel to another, loss is avoided by moistening a glass rod in the liquid, bringing it into contact with the lip of the glass or basin, and pouring the liquid down this rod, which is not removed until the side of the vessel is nearly restored to the vertical position; by observing this precaution we escape the risk of losing any portion from its running down the outside of the vessel. The drops adhering to the rod are washed into the rest of the solution.

The animal substances that we have to examine naturally arrange themselves into fluids and solids, and as this division is convenient in a practical point of view, I shall here adopt it, beginning with those presented to us in a fluid state.

In order to fix some definite limit to our enquiries, those principles only will here be noticed, which, from the frequency of their occurrence or their importance as constituents or products of the living frame, are most likely to be the special objects of attention to the physician and pathologist. In this number among the fluid products I shall enumerate fibrin, albumen, casein, fatty matters, urea, sugar, the uric, urobenzoic, lactic, and oxalic acids, mentioning a few other compounds, as ptyalin, sulphocyanic acid, &c. &c., when describing the general plan of analysing the secretions in which they most commonly occur.

A. Analysis of animal fluids.

When an animal fluid is presented for analysis, it is necessary in the first place to acquire a knowledge of the ingredients which enter into its composition in order to be able to decide upon the best method of ascertaining their proportions. The means of determining the nature and quantity of the organic constituents will be first described, leaving the saline matters for a subsequent section.

1. *For the organic constituents.*

It is possible that all the principles just enumerated may occur together; this, however, will very rarely happen unless we have to examine the contents of the stomach, when a still more heterogeneous mass may be presented to us.

Having, where practicable, taken the specific gravity of the liquid in order to acquire an idea of its degree of concentration, we place a portion under the microscope, and are thus enabled at once to decide upon the presence of blood globules, pus globules, fatty or oily matters in suspension, the debris of tissues, crystals of various substances, as uric acid, cholesterin, &c., and may then pass to tests purely chemical for its

Qualitative analysis.

a. By allowing the liquid to stand at rest for a few hours, we at once determine the presence of *fibrin*, which coagulates and separates spontaneously, at the same time enveloping the red globules and suspended particles in its meshes.

b. The clear liquid is heated to boiling; if *albumen* be present it coagulates, unless the solution be alkaline, when the addition of a few drops of nitric acid causes an immediate curdling. A drop or two of acetic acid added to the original liquid, if it produce coagulation, shews the presence of *casein*. We need not seek for casein if the fluid shews an acid re-action, as it is coagulated by free acids in general. If *mucus* be present, some ambiguity may arise from the action of acetic acid, as this re-agent causes the coagulation of the mucus furnished by the alimentary canal and its appendages. When present, however, in appreciable quantity, mucus always communicates to the fluid a certain degree of ropiness which leads us to suspect its presence. A confirmatory test for casein under such circumstances consists in adding a few grains of milk sugar and a little washed rennet; if the mixture be heated for an hour or two to about 120°, the casein coagulates completely.

c. Fatty matters and cholesterin are revealed by the microscope, and may be separated by evaporating the fluid to dryness, digesting the residue with ether and filtering; by spontaneous evaporation of the ethereal solution, they are left behind with their usual physical characters.

d. The presence of *sugar* is best discovered by mixing the suspected fluid with yeast and placing it in an inverted tube over mercury for twenty-four hours, at a temperature of from 70° to 80° F., making at the same time a comparative experiment with an equal bulk of the same yeast diluted to the same extent with pure water. We cannot by yeast determine with certainty the presence of sugar in a proportion less than $\frac{1}{200}$th of the liquid employed. A much more delicate test, and one which furnishes more immediate results, has lately been proposed by Trommer, founded upon the fact that organic bodies, to which free alkali has been added in excess, and especially solutions of grape and milk sugar, dissolve freshly precipitated oxide of copper; when the saccharine solutions are boiled they are decomposed, and sub-oxide of copper is deposited of a characteristic reddish brown colour. To apply this test, add to the suspected liquid a few drops of solution of caustic potass, so as to render it distinctly alkaline, then a small quantity of a dilute solution of sulphate of copper, agitating to dissolve the precipitate; a liquid of a blue colour varying in intensity with the quantity of copper held in solution is obtained. Apply heat, and if sugar is present an ochre yellow or red precipitate of sub-oxide takes place, as soon as ebullition begins. I have already mentioned that the presence of milk sugar has the same effect as grape or diabetic sugar; other animal matters produce a similar change. It is, however, very delicate in its indications; a negative result therefore may be considered as decisive of the absence of sugar. If a precipitate occur, the presumption that we are examining a saccharine liquid ought always to be confirmed by recourse to the unequivocal expedient of fermentation. It is easy to concentrate the fluid if the sugar is very small in quantity; the only case in which any ambiguity can arise. *Sugar of milk* has never been found but in the secretion from which it derives its name.

e. Urea can only be discovered satisfactorily by evaporating the suspected fluid to dryness and treating the residue with alcohol, again evaporating this alcoholic solution to dryness, redissolving in water, and adding nitric or oxalic acid with the precautions to be mentioned hereafter when treating specially of the determination of urea. When common salt is allowed to crystallize from a moderately dilute solution of urea, the form of the crystals is modified, and instead of obtaining cubes or octohedra the crystals developed assume a more or less penniform appearance, often shewing the figure of a Maltese cross with serrated edges. These modifications have been proposed as a test of the presence of urea: they are not, however, certain indications, though useful as affording a presumption of its presence. When a fluid which contains urea is concentrated by evaporation, and nitric acid is then added, by spontaneous evaporation on a glass plate we obtain lamellar crystals of nitrate of urea in irregular rhomboidal plates with the acute angles often truncated.

f. To detect the existence of *uric acid and the urates*, if albuminous principles are present, the liquid is evaporated to dryness, and the residue digested for some hours with solution of caustic potash, till every thing soluble has been taken up. It is diluted, filtered, and supersaturated with hydrochloric acid; a flocculent precipitate forms, which is redissolved by excess of acid; and the uric acid separates; this is collected on a filter. We are enabled by this process, where considerable quantities of uric acid are present, as in the excrements of birds of prey, to obtain results of considerable accuracy; but where the proportion of the acid is very minute, it cannot be relied upon for quantitative experiments; the residue in these cases must be subjected to microscopic examination. If no azotised matters are present, the mere addition of free hydrochloric acid after a lapse of some hours usually causes a separation of rhombic crystals of the acid; or by evaporating to dryness and treating the residue with water acidulated with hydrochloric acid, the uric acid remains undissolved; the residue is proved to contain this compound, either by the appearance of its crystals under the microscope, or by evaporating a small portion to dryness with nitric acid on a slip of glass, when a red stain is left; a drop of ammonia added produces a fine crimson; if this be evaporated to dryness, a drop of solution of caustic potash converts it into a beautiful purple, which is destroyed by the application of heat.

The methods for testing the other acids will be described when treating of their quantitative determination.

Having now obtained an idea of the nature of the fluid we have to examine, we are ready to proceed with its

Quantitative analysis.

A thin porcelain or platinum capsule is carefully counterpoised, and filled with a given weight of the fluid, usually 500 or 1000 grains.

This is evaporated to dryness in a water-bath. It is carefully weighed and the total solid contents determined; the loss indicates volatile matters consisting almost entirely of water. The residue is carefully incinerated with the usual precautions until all traces of carbon are removed: on weighing again we obtain the fixed saline constituents.

By this means we have determined

Water and volatile matters.

Organic matters and ammoniacal salts.

Fixed saline matters.

The quantity of each organic substance has now to be estimated. We have at present no absolutely exact method of determining all the ingredients from one portion only of a fluid; the following offers the nearest approximation.

a. Fibrin separates by spontaneous coagulation; it is washed and determined in the manner to be described hereafter.

b. If casein and albumen be both present, a given portion of the clear liquid is acidulated with a few drops of acetic acid, and evaporated to dryness in vacuo over sulphuric acid. The residue is digested with successive portions of water at 120°, as long as any thing dissolves; this residue is then dried upon a water-bath, pulverised, and treated with ether, by which all fatty matters are removed; casein alone remains behind. It is completely dried, weighed, incinerated, and the ashes deducted. This method of separating the casein is imperfect, as a portion of this substance generally redissolves on the addition of water. If uric acid be present, it will be found with the casein, which must be dissolved in solution of potash, diluted, filtered, supersaturated with acetic acid, by which the azotised matter at first precipitated is redissolved. Uric acid alone remains; it is collected on a weighed filter, and the quantity determined. It should always be tested by the microscope or by nitric acid.

c. The aqueous solution filtered from the casein, or the liquid for examination, if this principle be absent, is evaporated to dryness by a water-bath. If much fat is present, the residue is washed with ether to remove the greater part of the oily matter, then dried thoroughly, and powdered; an operation which, after the preliminary treatment with ether, may be effected without much difficulty. The pulverized mass is digested with ether, and the ethereal solutions, including that in which the casein was digested, are mingled and evaporated to dryness. Cholesterin, fatty matters, lactates, and a trace of urea are obtained; by digesting with water the cholesterin and fats alone remain and may be collected on a filter and weighed.

d. The residue, after digestion with ether, is treated with boiling water; the solution thus obtained may contain urea, sugar, sugar of milk, extractive and saline matters,—in short, every thing except the albumen, which is completely dried and then weighed. When no casein is present, the uric acid, if any, will accompany the albumen, and may be separated from it in the manner directed for its separation from casein.

e. The filtered liquid is evaporated to dryness and treated with a mixture of one part of anhydrous ether with two of absolute alcohol, by which urea, muriate of ammonia, lactates, the alcoholic extractive matters so called, and a small part of the sugar, are dissolved. The remainder of the sugar, sugar of milk, aqueous extractive matters, urates, sulphates, chlorides, and phosphates remain behind, forming residue (1).

f. The alcoholic solution is evaporated to dryness and weighed: the solid matter divided into two portions; one is dissolved in water acidulated with nitric acid, and treated with nitrate of silver, by which the chlorine is separated as chloride of silver, and hence the muriate of ammonia is determined; from the other portion we determine the quantity of urea by oxalic acid with the usual precautions. Having thus determined the weight of the muriate of ammonia and of the urea, we infer the deficiency to consist of a little sugar, lactates, and alcoholic extract.

g. The residue (1), which contains sugar, sugar of milk, watery extract, and salts, is boiled with proof-spirit as long as any thing is dissolved; the solution is evaporated to dryness, and if grape sugar be present, half the residue must be dissolved in water and fermented with yeast to determine the proportion of this substance, and its weight is deducted from the weight of the residue left on evaporating the spirituous solution; the other half residue is incinerated, and the quantity of saline matter ascertained; by deducting the weight of the sugar and salts we then obtain that of the sugar of milk, together with the alcoholic extract, from which we possess no exact means of separating it. It, however, very rarely happens that in the same fluid we meet with grape sugar and sugar of milk; the absence of sugar will obviously much simplify the method of proceeding.

h. The portion undissolved by proof-spirit is dried and weighed; it is incinerated and again weighed; the difference between the two weighings gives the quantity of watery extract.

This will be the general plan of operations if it be required to determine the quantity of each individual ingredient. From the number of operations required, and the destructible nature of the ingredients, the result, as already mentioned, is not rigidly accurate. Frequently, however, it is merely necessary to ascertain the proportion in which one substance only is found; the presence or absence of others being all that it is desired to know concerning them.

We proceed now to the special consideration of the different animal principles.

Fibrin.—Although the identity, in chemical composition, of fibrin, albumen, and casein has lately been strongly insisted on by Liebig and his pupils; yet, as in their physical properties at least, and in the offices they perform in the body, they differ considerably, it is frequently of great importance to determine the relative proportion of each in the fluids and secretions. These three principles occur both in the coagulated and uncoagulated state. When coagulated, the separation of fibrin and albumen cannot be effected by any means with which we are acquainted, and, indeed, the first authorities differ when they attempt to decide which of the two they have to deal with, if they occur in the coagulated state. When uncoagulated, their separation and quantitative determination may be effected with considerable accuracy. Pure fibrin, when moist, is white and somewhat elastic, is insoluble in water, alcohol, or ether. It is readily taken up by strong acetic acid, and from this solution it is precipitated by ferrocyanide of potassium (prussiate of potash); fibrin also dissolves in solution of potash; if, when thus dissolved, it be heated gently and the liquid neutralized by an acid, a white flocculent precipitate occurs, which redissolves in excess of acid, and the solution emits an odour of sulphuretted hydrogen. Strong nitric acid turns fibrin yellow, forming a yellow solution with gradual evolution of gas; in concentrated hydrochloric acid it slowly dissolves with a rich violet colour. These are properties it possesses in common with albumen and casein; but it is distinguished from them and from all other animal matters by its spontaneous coagulation when removed from the living body. This furnishes us with a certain test of its presence when in the liquid form, and enables us to separate it in good degree from other bodies; within its pores, however, is obstinately retained a quantity of the fluid from which it has just separated itself, together with most of the globules and particles suspended in the secretion. It becomes necessary, therefore, to wash out these ingredients, an operation rendered possible by the insolubility of the fibrin in cold water. The coagulum from a known quantity of fluid is cut into very thin shreds by a sharp knife, tied in a piece of linen, and a gentle stream of water allowed to fall upon it; from time to time the clot is gently kneaded and the washing continued; in the case of blood, till all traces of colouring matter are removed, or, where no colour is present, so long as may be deemed necessary; the residue is then removed from the linen, dried, digested in ether to remove adhering fatty matters, again dried and weighed. A portion is then incinerated, the weight of the fixed matters determined and deducted from the gross weight of the dried fibrin, by which we obtain that of the organic matter.*

Fatty matters.—Several peculiar oily substances occur in the fluids and solids of the animal body. Among the saponifiable fats chemists have distinctly ascertained the presence of margarin, elain, and butyrin; besides these we have cholesterin and serolin, which are not saponifiable by boiling in alkaline solutions, and there are others containing phosphorus and sulphur, but their composition and properties are yet involved in uncertainty. Our analytical processes for separating these bodies are very imperfect; the fats are all soluble in boiling alcohol, and still more freely in ether. Cholesterin and serolin may be isolated from the other fats by boiling the residue, after evaporation of the ether, with solution of caustic potash, as they remain undissolved by this menstruum, whilst the margarin, elain, and butyrin form soaps which are dissolved by the water.

Serolin is an azotised fat, which has hitherto only been found in the blood; it is readily distinguished from cholesterin by its fusing point being much lower, 97° F., whereas cholesterin does not melt below 278°, and is found in the blood only in minute quantity. By pressing them between folds of filtering paper we might therefore, if careful to maintain a temperature near that of boiling water, effect a tolerably complete separation of these bodies.

Butyrin rapidly absorbs oxygen from the air, setting free a volatile acid, the butyric; it possesses the peculiar odour of rancid butter, by which its presence is always easily recognized.

In analytical inquiries it is best to separate fatty matters by ether as the first step after the liquid has been evaporated to dryness; we may then safely proceed to determine the

Albumen.—In chemical properties it differs little from fibrin, excepting in the fact of its requiring heat or some chemical agent to produce coagulation; towards reagents it comports itself in the same way. When liquid, its separation from fibrin and fats is effected as just described. The residue, after the fats have been removed by ether, is digested in boiling water, and the residue well washed; the albumen remains upon the filter, and must be dried and weighed. A given quantity is incinerated to determine the proportion of saline matters, which must be deducted from the weight previously found. If uric acid existed in the solution, it would be mixed with the albumen. In case the colouring matter of the blood were contained in the fluid, a small part would remain mixed with the albumen, and might be removed by digestion in alcohol acidulated with sulphuric acid, by which the hæmatosin is dissolved; the greater part, however, subsides by allowing the liquid to stand undisturbed in a tall vessel for forty-eight hours. If the solution contain free alkali, a part of the albumen is redissolved on the addition of water; when, therefore, the filtered liquid presents an alkaline reaction, it should be very carefully and exactly neutralized by acetic acid, evaporated to dryness, and again treated with hot water; the weight of this second portion of albumen must be added to that first obtained. Casein hardly ever occurs in the same solution with albumen; if present, it would be separated by the acetic acid in the manner already described.

Casein is distinguished from albumen by its non-coagulability by heat; when its solutions are evaporated at a high temperature, an insoluble skin or film forms upon the surface, which is almost characteristic, the only thing

* It has been objected that the insoluble nuclei of the red particles are retained in this process. It is, however, superior, both in the accuracy of its results and the facility of its performance, to any other method hitherto proposed as its substitute.

with which it can be confounded being an alkaline solution of albumen, which resembles it in this and in some other particulars. Acetic acid in small excess causes its immediate coagulation; a great excess of the acid redissolves the coagulum. The fibrin, fats, and albumen having been separated in the manner already described, we may proceed to determine the casein by adding a few drops of acetic acid and evaporating to dryness. Boiling water removes from the residue every thing except saline matters and casein; this residue is dried, weighed, incinerated, and the salts deducted; a portion of casein is apt to redissolve in the water, so that this process is not perfectly accurate.*

Urea.—It is best, when practicable, to make a separate analysis for this principle; if this be impossible, we may proceed with the fluid from which albumen, casein, and fats have been separated, as already mentioned. In either case the liquid is evaporated to dryness, and the residuum digested with alcohol; we thus obtain a solution of urea freed from every thing except chlorides, sugar, some "extractive" matters, besides fats and lactates, unless previously removed by ether. The alcohol having been driven off, the residue is dissolved in sufficient water to produce a liquid of syrupy consistence. Colourless nitric acid is diluted till of a specific gravity of 1·25, which is a convenient strength for precipitating the nitrate of urea. The evaporating basin with the impure solution of urea is next placed in a vessel containing a frigorific mixture composed of 1 oz. of nitre, 1 of sal ammoniac, each finely powdered, and 4 oz. of water; when the basin and its contents have been thus cooled, colourless nitric acid, sp. gr. 1·25, rather more than equal in bulk to the solution of urea, is added drop by drop, stirring carefully; if added too quickly, the temperature rises, a little effervescence ensues, and part of the urea is decomposed. A flaky precipitate shows nitrate of urea; the whole is allowed to remain in the freezing mixture for three or four hours, or even longer; the nitrate of urea is then collected on linen, the linen is folded up, placed between several layers of filtering paper, and then subjected to strong pressure. The mother-liquor and excess of acid are thus almost entirely expelled; a slightly discoloured firm dry mass of nitrate of urea is procured, which may be exposed for some time to a temperature of 212°, and then weighed; 100 parts contain 48·78 of urea. The amount of impurity which this nitrate contains is usually very small, as is easily proved by ultimate analysis.

The nitrate of urea crystallizes in flat rhomboidal tables, is sparingly soluble in water, pretty freely in alcohol even when cold, very slightly in pure ether. It is wholly volatilized by heat; when digested with carbonate of baryta suspended in water, effervescence ensues; on evaporating to dryness, exhausting with hot alcohol and evaporating slowly, long prisms of urea are obtained.

Other methods have been proposed for estimating the urea, and when the proportion is small the substitution of oxalic for nitric acid furnishes results of greater accuracy; but the urea must then be separated by *absolute* alcohol instead of rectified spirit from its other accompaniments; the oxalic acid is rubbed to a thin cream with water, and a portion of this, equal in bulk to the syrupy solution of urea, is added to the liquid, which is gently warmed; it is then allowed to cool, and the whole immersed in the frigorific mixture. The crystals are drained on calico and subjected as before to strong pressure; the firm dry cake of oxalate of urea and oxalic acid is allowed to digest at a temperature of 100° F. for about eight hours, with rather more than its own weight of chalk and six or eight times its weight of water. Effervescence ensues, an insoluble oxalate of lime forms, and urea is dissolved; the solution is filtered and evaporated to dryness; long crystals of nearly pure urea form, from the weight of which the quantity is ascertained: they ought to dissolve completely in absolute alcohol; anything undissolved is oxalate of ammonia.

If the amount of urea be very small, as is sometimes the case with diabetic urine or the serum of the blood, Dr. Rees recommends the employment of ether instead of alcohol to the dry residue. Urea is very sparingly soluble in this menstruum and will be obtained with the fats; the ethereal liquid evaporated and the residue treated with water, filtered and again evaporated, furnishes long delicate prisms of urea; this process, however, must be regarded more as a test of the presence of urea rather than as a means of estimating its quantity. Sometimes urobenzoic (hippuric) acid occurs in diabetic urine, and it would then be extracted by ether along with the urea and crystallize with it; but it is easily separated and distinguished by the sparing solubility of its crystals in cold water.

Sugar.—It is best to take a separate portion of the fluid to determine the quantity of sugar. A jar, with its aperture ground smooth, graduated to tenths of a cubic inch, and capable of containing from 12 to 20 cubic inches, is turned with its mouth upwards and filled to within an inch or two of the top with mercury; from 100 to 200 grs. of the liquid for analysis is accurately weighed and transferred to the jar with the usual precautions; 8 or 10 grs. of yeast are introduced, and the jar accurately filled with water; the mouth is closed by a glass valve, which is retained in its place by a piece of linen or any other convenient means; the jar is inverted in a basin of mercury and the valve removed. The apparatus is set aside for two or three days in a temperature of about 70°, till the fermentation is complete. The quantity of gas is now accurately read off; the temperature of the room and height of the barometer carefully noted, as well as the difference between the level of the mercury within and without the jar. As the liquid will be saturated with

* Proof-spirit may be substituted for water as a solvent, but it leaves more animal extractive matter, though it dissolves less of the casein.

its own bulk of carbonic acid at the observed temperature and pressure, we must in our calculations add the bulk of the liquid to that of the gas actually observed. Having reduced the bulk of gas to the standard pressure of 30 inches and the temperature of 60° F., according to the rules given in all works on physics, we deduce the quantity of sugar, since 100 cubic inches of carbonic acid are furnished by the decomposition of 106·6 grs. of grape sugar.

If mercury be not at hand, we may, by adapting a tube containing chloride of calcium, and a bulb apparatus charged with strong solution of potash,* the weight of which is accurately known, to a tubulated retort, obtain a result of considerable accuracy. In a half-pint retort, so adjusted, 500 grs. of urine are placed, and 30 or 40 grs. of yeast added; through the tubulure of the retort a straight tube passes, and dips below the surface of the fluid; the upper extremity is closed by a cork. It is set aside to ferment at a temperature of 70°; the chloride of calcium retains the moisture, and the potash ley absorbs the carbonic acid; by the increase of weight we know the quantity of carbonic acid formed. As at the close of the experiment the apparatus will be full of carbonic acid, it must be displaced by removing the cork from the straight tube passing through the tubulure of the retort, and then gently drawing air through the apparatus for some minutes by careful suction at the extremity of the potash apparatus, in the manner to be described presently when treating of the process of ultimate analysis. 100 grs. of carbonic acid indicate 225 grs. of diabetic sugar.

Another method of ascertaining the quantity of sugar consists in adding to a given quantity of the fluid a known weight of yeast—having by experiment determined the quantity of fixed matter contained both in the yeast and in the fluid operated on. After fermentation is complete the solution is evaporated to dryness, and the loss of solid matter sustained indicates the quantity of sugar which has passed off as alcohol and carbonic acid; the urea likewise is destroyed in the process, and its quantity must be deducted from the total loss. It is very desirable when sugar is present in considerable quantity that the evaporation to dryness should be performed in vacuo over sulphuric acid, as it is the only method that ensures our obtaining the sugar always in the same state of hydration. This process, however, is tedious, always requiring many days for its completion: some comparative experiments, showing the value of this precaution, will be detailed hereafter.

Our methods of exactly determining the quantity of sugar of milk are imperfect; I shall describe the plan which answers best when treating of the analysis of milk.

Uric acid.—This is one of the most interesting and important animal products from the part it frequently performs in some of the most serious and distressing diseases to which we are liable. The method of detecting its presence by evaporation on glass with nitric acid has already been described. When no albuminous principles are present, the solution is evaporated to dryness and the residue treated with water, acidulated with hydrochloric acid; the insoluble portion is dried and weighed, then burned; the weight of the remaining ash (silica), if any, is deducted; the loss indicates the quantity of uric acid.

Urobenzoic, or, as it is often called, *hippuric acid*, has hitherto been found only in the urine, in which it generally exists in minute quantity, according to Liebig. Its quantity may be ascertained by adding hydrochloric acid to the liquid concentrated by evaporation. It is evaporated to dryness by a water heat, and the residue digested with pure anhydrous ether as long as any thing is dissolved. By spontaneous evaporation it is left behind nearly pure, and may be weighed; traces of urea crystallize with it, and a little of the odorous principle, which obstinately adheres to it. If the ether have dissolved any fatty matter, the addition of boiling water will dissolve the acid and leave the fats. Urobenzoic acid may be detected by heating a crystal in a test tube; benzoic acid and benzoate of ammonia, and a few red drops of an oily matter, sublime, accompanied by a smell of bitter almonds and of the Tonka bean. Alcohol dissolves it freely, and the solution by evaporation leaves stellated groups of needle-shaped crystals. With perchloride of iron solutions of the urobenzoates furnish a cinnamon brown precipitate.

Lactic acid cannot be quantitatively determined without difficulty. The best method is as follows:—The solution if acid is neutralized with ammonia, evaporated to dryness, and the residue exhausted with alcohol; to the filtered liquid sulphuric acid is added drop by drop as long as a precipitate ensues; the bases are thus removed as sulphates. The solution is filtered and the precipitate washed with alcohol; the clear liquid is digested with frequent agitation, at a moderate heat, for twenty-four hours, with carbonate of lead: hydrochloric, sulphuric, and phosphoric acids are thus separated as insoluble salts, while lactate of lead dissolves. The solution is a second time filtered, sulphuretted hydrogen gas transmitted through the clear liquid, and the sulphuret of lead separated by another filtration; the filtered fluid is evaporated to dryness to expel the alcohol and excess of gas, the residue redissolved in water and digested with carbonate of zinc; by evaporation of the filtered liquid crystals of lactate of zinc are obtained. If the solution is now mixed with carbonate of potash in excess, evaporated to dryness, exhausted with boiling water and the residue dried and ignited, pure oxide of zinc is obtained: 100 grs. of this oxide indicate 202.5 grs. of lactic acid.

If *oxalic acid* be suspected in any liquid, it must be super-saturated with lime water. On treating the precipitate with acetic acid the phosphates dissolve, and oxalate of lime re-

* These pieces of apparatus will be described in detail in the directions for the performance of ultimate analysis.

mains, as the phosphate of iron is insoluble in acetic acid. The absence of iron must be determined by dissolving the precipitate in nitric acid, nearly neutralizing with ammonia and adding hydrosulphuret of ammonia; the iron, if present, would fall as a black sulphuret, mixed with oxalate of lime. Oxalate of lime dissolves in dilute nitric acid, and, on supersaturating with ammonia, is thrown down unchanged. By converting the oxalate of lime into the carbonate or sulphate, as directed when speaking of the estimation of lime, the quantity of oxalic acid may be inferred—100 grs. of the carbonate indicate of anhydrous oxalic acid 72 grs., and 100 of the sulphate 51.94 of the acid.

2. *For the inorganic constituents.*

To ascertain the nature and proportion of the saline matters incineration is resorted to in the manner already described. This process, however, only tells us what the *fixed* ingredients are, and their quantity, in the form of oxides, chlorides, sulphates, phosphates, or carbonates. All the ammoniacal salts are necessarily dissipated, frequently carrying off portions of sulphuric acid and chlorine. The organic acids that may have been combined with the bases are entirely decomposed and their place supplied by carbonic acid, which renders it difficult to decide whether any carbonate actually existed as such in the compound; and moreover the metals, as iron, calcium, and magnesium, with other bodies, as sulphur and phosphorus, are for the most part estimated, not (as is sometimes probable, and at others certain, that they existed) in the metallic or unoxidized form, but as oxides or acids. The information we derive from incineration is therefore incomplete, and the mere deduction of the weight of ashes from the entire weight of the body burned by no means furnishes us with a correct estimate of the proportion of volatile ingredients; generally speaking, however, it is the nearest approximation we can obtain.

I shall here describe very briefly the means best adapted to the qualitative and quantitative determination of the saline matters, referring those requiring more ample instruction on this subject to Rose's Manual of Analytical Chemistry, and the various systematic treatises on the science.

Although during incineration portions of saline matter, and especially of chlorine, are carried off, and the sulphates are sometimes reduced to sulphurets, we find it the only method by which any thing like an accurate estimate of the inorganic constituents can be obtained, inasmuch as many of these bodies occur in the form of chemical compounds with organic matter, and are thus prevented from forming precipitates with the ordinary reagents: iron is particularly liable to be thus affected. When practicable, we should usually make an analysis of the solution for the inorganic acids before evaporation, and afterwards a second examination of the fixed residue after ignition.

The inorganic materials for which we shall have in general to search are comparatively few in number; among the acids, hydrochloric, sulphuric, phosphoric, and carbonic, with traces of silica, will be those of most frequent occurrence. Occasionally we may have to seek for iodine, fluorine, and unoxidized sulphur. Potash, soda, ammonia, lime, magnesia, and oxide of iron, are the bases that will be most frequently the objects of experiment, and now and then we may have to look for copper, lead, and some other metals.

Qualitative examination.

a. The saline residuum, after ignition, is boiled with a little water (solution A) and filtered from the insoluble residue (B).

A. *b.* The solution, except in special cases, will only contain sulphates of potash, soda, lime, and magnesia, as well as chlorides of the same bases, and phosphates and carbonates of potash and soda. When the alkaline carbonates are present, lime and magnesia need not be looked for; nor need we search for either of these bases if the solution contain phosphates, unless the liquid reddens litmus paper. The liquid is, therefore, in the first place tested with blue and with reddened litmus paper, by which acidity, alkalinity, or neutrality is rendered evident; we then proceed to determine what acids are present. The absence of a precipitate should not be too hastily decided on. As a general rule the tests should be allowed to stand twelve hours before a negative result is recorded.

c. A portion of the liquid is acidulated with nitric acid, and to a small quantity of it a drop or two of solution of *chloride of barium* added; a white cloud indicates *sulphuric acid.*

d. Into another portion of the acidulated fluid *nitrate of silver* is dropped in slight excess; a bluish white flocculent precipitate shews the presence of *chlorides.*

e. The solution (*d*) is filtered from the chloride of silver, is boiled for a few minutes, then saturated exactly with ammonia. If *phosphoric acid* be present, a yellow precipitate of phosphate of silver, very soluble in excess of ammonia, is produced.

f. A little of the aqueous solution is evaporated to dryness, and a drop of *nitric acid* added to the residue: effervescence indicates *carbonic acid,* due in all probability to the decomposition of some organic acid by ignition.

We have next to test for the bases in solution.

g. The liquid is rendered slightly alkaline by *ammonia* free from carbonate.* A white precipitate shews *phosphate of lime* or *magnesia,* or both.

h. The filtered liquid is tested by *oxalate of ammonia;* if *lime* be still in solution, a white cloud falls.

i. The oxalate of lime is separated by filtration and *phosphate of soda* or ammonia added; brisk stirring with a glass rod causes a white

* The absence of carbonic acid is easily ascertained by adding some lime-water to the solution of ammonia; it ought to remain perfectly transparent; opalescence indicates the existence of carbonic acid.

crystalline precipitate if any *magnesia* were still contained in the liquid.

k. A portion of the original liquid *(b)* is acidulated with a drop or two of hydrochloric acid; if sulphuric or phosphoric acid have been detected (by *c* and *e*), chloride of barium in slight excess is added, the solution filtered, heated, and precipitated by a mixture of caustic and carbonate of ammonia; it is again filtered, the liquid evaporated to dryness and ignited, the residue dissolved in alcohol, and sufficient alcoholic solution of bichloride of platinum added to produce a yellow liquid: a yellow precipitate indicates *potash*. If no sulphuric or phosphoric acid be present, the use of the chloride of barium and ammonia will become unnecessary.

l. Decant the yellow solution just obtained *(k)* from the precipitate, if there be any, and allow it to evaporate spontaneously or at a very gentle heat. If *soda* be present, long prismatic yellow needles of the double chloride of platinum and sodium form. This is the best test of the presence of soda. The yellow tint which its salts communicate to the exterior flame of the blowpipe, when heated on a platinum wire, has been proposed, but this is by no means an unequivocal appearance. Almost all the animal fluids contain soda in the form of common salt.

B *m.* The insoluble fixed residue (B) may contain phosphates and carbonates of lime and magnesia, as well as phosphate and oxide of iron, and traces of silica. The residue is treated with nitric acid, by which every thing but the *silica* is dissolved. *Carbonic acid*, if present, is manifested by effervescence.

n. The solution is diluted and filtered; to one portion ammonia free from carbonic acid is added; if phosphoric acid be present, a precipitate occurs whilst the liquid still remains acid; under these circumstances ammonia is added as long as the precipitate at first formed re-dissolves in the solution, still acid. If a solution of *acetate of lead*, carefully dropped in, cause a white precipitate, soluble in nitric acid, and which if collected and dried fuses before the blowpipe into a semi-transparent bead, which assumes a crystalline structure on cooling, *phosphoric acid* is indicated by the phosphate of lead thus obtained.

o. Another portion of the acid liquid is neutralized by ammonia, and the precipitate, if any occur, re-dissolved by acetic acid. Oxalate of ammonia shews *lime* by the formation of a white precipitate.

p. To the liquid filtered from the oxalate of lime *carbonate of ammonia* is added in slight excess; if the previous examination have shewn phosphoric acid to exist, a crystalline precipitate indicates the double phosphate of ammonia and magnesia. If no precipitate be thus obtained, boil the liquid, and the *magnesia* in solution falls as carbonate.

q. Oxide of iron is detected instantly by adding a drop of solution of *ferrocyanide of potassium* to the acid solution: an immediate Prussian blue precipitate shews iron, if present. The precipitates obtained in the previous experiments for lime and magnesia will, instead of being white have a more or less decided rusty brown tint, especially when dry, if iron form any considerable part of the matter examined.

For the detection of iodine, lead, and the other bodies enumerated in the list of inorganic substances for which we may occasionally have to look, the reader is referred to the following directions for the *quantitative estimation* of the different compounds.

Quantitative estimation.

For the convenience of analysis our saline matter may be divided into two portions, one of which is employed for determining the acids, the other for the bases. The first portion will enable us to ascertain the quantity of carbonic and phosphoric acids, of chlorine, and of sulphuric acid. From the second portion we obtain the potash, soda, lime, magnesia, iron, and alumina, if, as rarely occurs, the latter be present.

Other ingredients will usually be matter of special examination; the details of the methods to be pursued are subjoined.

We begin by treating the salts to be examined with water (solution A). Nothing but carbonates and phosphates of the earths will thus remain undissolved (residue B).

(A.) *Carbonic acid.*—The aqueous solution is treated with lime-water, or with a mixture of ammonia and *nitrate* of lime, as long as any precipitate is produced. If no phosphates be present, this consists of carbonate of lime, the solution is boiled—filtered, the precipitate ignited, and after adding a few drops of strong solution of carbonate of ammonia heated below redness and weighed, 100 grs. of carbonate of lime indicate 44 of carbonic acid. When phosphates are present, we proceed as follows:—

Phosphoric acid.—The precipitate obtained by lime-water, as thus directed, contains all the phosphoric acid that may be present. If therefore phosphates existed in our solution, the precipitate, after its weight has been carefully ascertained, must be dissolved in nitric acid, and caustic ammonia (free from carbonic acid) added in slight excess. The phosphoric acid separates as a gelatinous precipitate of phosphate of lime. It must be ignited and the weight deducted from that of the mixed precipitate previously obtained; the difference indicates the quantity of carbonate of lime. The precipitated phosphate of lime contains 49·1 per 100 of phosphoric acid. Phosphate of lime dissolves in nitric, hydrochloric, or acetic acid without effervescence, and is thrown down by ammonia in a gelatinous form. The phosphates and carbonates being thus separated, the filtered solution is treated for,

Hydrochloric acid.—The quantity of this acid or of the chlorine it contains may easily be determined by precipitating the solution pretty strongly acidulated with nitric acid by means of nitrate of silver. The chloride of silver thus obtained is completely soluble in ammonia, but resists the action of strong nitric acid even when boiling. The precipitate must be ignited; it should undergo fusion into a horny mass at a heat a little below redness. It is now weighed; 100 parts indicate 25 of chlorine.

Sulphuric acid may be precipitated from the filtered liquid or from any fluid suspected to contain it by acidulating (if not already acid), not too strongly, with nitric acid, and precipitating with nitrate of baryta. The precipitate should be well washed with boiling water as long as any thing is dissolved, then ignited and weighed. Boiling nitric acid is without effect upon it; 100 grs. contain 34.19 of sulphuric acid.

(B.) The insoluble portion consists of carbonates and phosphates of the earths, and perhaps of iron. We bring them into solution by means of nitric acid, and supersaturate with caustic ammonia to separate the phosphates; filter if necessary, and add oxalate of ammonia; collect and ignite the precipitate, moisten with solution of carbonate of ammonia; it is once more heated to incipient redness, and it then consists of carbonate of lime: the carbonic acid is estimated in the manner already directed. The filtered liquid is boiled with solution of carbonate of ammonia; the magnesia, if any, precipitates and must be strongly ignited; 100 parts indicate 110 of carbonic acid, which must be added to that combined with the lime.

Phosphoric acid.—The quantitative estimation of this body is attended with some difficulty, as it cannot be effected by direct precipitation, but is inferred from the loss. The precipitate by caustic ammonia just obtained consists entirely of earthy phosphates and phosphate of iron. It is ignited and the weight ascertained. It is then brought into solution by means of concentrated hydrochloric acid, and ammonia added until the precipitate from the still acid solution is no longer perfectly redissolved. Acetic acid is now added and then more ammonia, taking care that the liquid is still strongly acid. Phosphate of iron alone precipitates; this is separated by filtration, and after strong ignition consists of 57.44 phosphoric acid and 42.56 sesquioxide of iron. From the filtered liquid the lime and magnesia are separated by oxalate of ammonia and caustic ammonia, as will presently be described; then deducting the united weight of the oxide of iron, lime, and magnesia from that of the ignited mixed phosphates, the remainder is phosphoric acid.

In order to bring the tests for analogous bodies together, I shall here interrupt the course of the analysis to describe the methods of proceeding with those substances for which occasionally, though more rarely, we have to look.

Iodine, in organic fluids, always occurs in the form of an iodide, and is not met with in the human body in its normal condition. We must evaporate to dryness and treat the residue with alcohol. The iodide will be dissolved; we again evaporate to dryness and re-dissolve in water: (if the quantity be not very minute, this preliminary process may be dispensed with, merely concentrating the liquid and allowing it to cool;) iodine may now be detected by adding a little cold solution of starch, and pouring into the mixture a few drops of solution either of chlorine or of chloride of lime (bleaching liquor), when a blue colour, more or less intense, is produced. The quantitative estimation of iodine in these analyses is seldom required; when it is, a neutral solution of chloride of palladium is added to the solution, accurately neutralized, and the whole set aside in a warm place for twenty-four hours, a black precipitate of iodide of palladium forms: it should be collected on a weighed filter and dried at a very gentle heat, otherwise part of the iodine escapes. 100 grs. of iodide of palladium contain 70 of iodine. By suspending this iodide in water and adding starch and a little chlorine water, the blue colour is produced as usual.

Fluorine, when present, and it appears to be a universal constituent of bones, is always in exceedingly minute quantity. To discover it we incinerate the dried matter, pulverize and make it into a thin cream with oil of vitriol in a shallow platinum crucible; instead of its usual cover the mouth is closed by a piece of flat glass, the under surface of which has been covered with a film of melted bees' wax or some resinous varnish; when firm or dry, a few characters are traced with a sharp point to expose the glass underneath; the glass is pressed upon the crucible so as completely to close it, and the whole heated over a spirit-lamp for a quarter of an hour. The glass is kept cool by a piece of moistened paper. If any fluorine be present, the traces upon the glass from which the wax has been removed will be more or less corroded; the superfluous wax may be removed by oil of turpentine, and the corrosion may be rendered distinct by rubbing a little powdered charcoal over the surface. If any marks are produced, it is an unequivocal proof of the presence of fluorine. This method, however, is not very delicate.

Free *sulphur* is detected by boiling the substance with solution of potash; if this element be present in the unoxidized state, a black precipitate of sulphuret of lead is formed on adding a few drops of acetate of lead.

If we desire to know the quantity of free sulphur, we first satisfy ourselves of the absence of sulphuric acid, or determine its quantity accurately by the method already described; then deflagrate the substance or dry residue with eight parts of pure nitre and two of pure carbonate of potash, throwing the mixture in successive small portions into a platinum crucible heated to redness; the sulphur is thus converted into sulphuric acid at the expense of the oxygen of the nitre, and its quantity may be determined by dissolving the saline residue in water, supersaturating with nitric acid, and precipitating by a salt of baryta as usual: the process is one requiring more than ordinary care to ensure accuracy.

To resume the usual process of analysis, we now proceed to determine the bases. Most of the acids may be determined with considerable exactness before the organic matter has been destroyed by ignition; it is not so with the bases. Incineration should always precede an attempt to estimate them. The second portion of saline matter is dissolved in water as before, separating it thus into a solution (A), and an insoluble residue (B).

(A.) *Potash.*—The solution rarely contains any but the alkaline salts. If, however, any of the earths are present, they must first be separated in the form of carbonates, by adding a mixture of carbonate and caustic ammonia; the filtered liquid is evaporated to dryness, the residue ignited to expel ammoniacal compounds and re-dissolved in water, which then contains only salts of potash and soda. If sulphuric or phosphoric acids be present, it is necessary for a quantitative determination of each alkali to convert the mixed sulphates or phosphates into chlorides. The method for accomplishing this object is rather circuitous: chloride of barium in slight excess is added to the solution, which is filtered from the sulphate or phosphate of baryta that then precipitates; the filtered liquid is heated with a mixture of caustic and carbonate of ammonia, again filtered, evaporated to dryness, and ignited; the bases are thus obtained in their desired condition of chlorides; they are then carefully weighed, re-dissolved in a small quantity of water; bichloride of platinum in solution is added, and the whole evaporated to dryness on a water-bath. The dry residue is digested with rectified spirit, and the washing continued as long as the liquid passes coloured through the filter; the precipitate, consisting of anhydrous double chloride of platinum and potassium, is dried and weighed; 100 grs. indicate 19.43 of potash.

Soda.—After the potash has been determined, the corresponding quantity of chloride of potassium is deducted from the weight of the mixed chlorides, and the deficiency inferred to be chloride of sodium; 100 grs. of chloride of sodium correspond to 53.33 of the anhydrous alkali. The platino-chloride of sodium, which the alcoholic solution contains, crystallizes in bold, well defined, flattened prisms readily soluble in water.

Ammonia, when present in organic fluids, cannot be quantitatively determined with accuracy. Its presence is easily recognized by the characteristic pungent fumes which are given off when the residue of evaporation is mixed with caustic potash and gently warmed.

(B.) *Iron.*—The precipitate by carbonate and caustic ammonia from A and the insoluble residue B are dissolved in hydrochloric acid. When no phosphates are present, the acid solution is nearly neutralized by caustic ammonia; then an excess of hydro-sulphuret of ammonia added; the iron falls as a black sulphuret. This is collected on a filter, washed, re-dissolved in hot hydrochloric acid, and the iron thrown down as sesquioxide by ammonia in excess. It is thus completely separated from lime and magnesia.*

If the earthy phosphates are present in mixture with iron, the process already described, when speaking of phosphoric acid, must be employed.

Lime.—The acetic solution of the phosphates filtered from the iron, or if no iron be present, the acid solution supersaturated with ammonia and the precipitate re-dissolved in acetic acid, (a precaution indispensable, as oxalate of lime is soluble in nitric or hydrochloric acids,) is treated with solution of oxalate of ammonia in excess. A white precipitate of oxalate of lime falls; it is allowed to stand some hours in a warm place (the liquid would otherwise pass turbid through the filter), separated by filtration, ignited, and then moistened with a saturated solution of carbonate of ammonia, after which it is thoroughly dried at a temperature short of redness. Carbonate of lime is thus obtained; 100 grs. contain 56 of pure lime.

Magnesia.—The filtered liquid is supersaturated with ammonia, well agitated, and allowed to stand for some hours; if any magnesia be present, it separates as a crystalline precipitate, which must be washed with a weak solution of phosphate of ammonia; it is dried and ignited; the residue contains 35.71 of magnesia in every 100 grs.

Our ordinary analysis terminates here.

Lead is sometimes found as a morbid constituent of certain parts, more particularly of the soft solids; the fluid or part to be examined is dried and incinerated, (if bulky, in a clean earthen crucible,) and the charcoal burned off as far as may be; the residue is digested in nitric acid diluted with thrice its bulk of water, filtered, nearly neutralized by ammonia, and a current of sulphuretted hydrogen transmitted through the liquid. The gas is easily generated for this purpose by adapting to a common phial a glass tube bent twice at right angles, one limb being considerably longer than the other; the short limb passes air-tight through the cork of the phial, and the other plunges nearly to the bottom of the liquid to be examined. In the phial 100 or 200 grs. of coarsely bruised proto-sulphuret of iron are placed, and an ounce or two of dilute sulphuric acid (1 of acid and 5 or 6 of water); abundant effervescence arises from the disengagement of the sulphuretted hydrogen. If lead be present in the tested liquid, a brown or black precipitate of sulphuret of lead falls, and the liquid becomes milky from the partial decomposition of the gas; when it smells strongly of the sulphuretted hydrogen, the liquid is filtered, the precipitate is treated with nitric acid, to which a few drops of sulphuric acid have been added, and the whole ignited; a white residue of sulphate of lead is obtained, which contains 68.42 per cent. of metallic lead. Sulphate of lead is insoluble in acetic acid, but is completely dissolved by a strong solution of acetate of ammonia.

* In the rare instances in which *alumina* presents itself in the animal fluids, this earth would precipitate along with the sulphuret of iron, and would again be thrown down with the sesquioxide. It is however easily separated by digesting the oxide while still moist in a solution of caustic potash; the oxide of iron alone remains behind. To separate alumina from the alkaline liquid, it is feebly supersaturated with hydrochloric acid, and again rendered slightly alkaline by ammonia; the alumina precipitates, is collected on a filter, thoroughly washed, ignited, and weighed.

The presence of *copper* is determined in the same way by incineration, treatment with nitric acid and sulphuretted hydrogen; the resulting sulphuret is dissolved in nitric acid, and the oxide thrown down from the boiling solution by excess of caustic potash: it is ignited and weighed; 100 parts contain 80 of metallic copper. If the nitrate of copper be treated with ammonia instead of potash in excess, a beautiful transparent blue solution is obtained, which, when procured as just mentioned, is characteristic of the presence of copper.

Mercury, arsenic, antimony, and a variety of other substances may occasionally be met with after poisoning with these bodies; but abundant directions for their discovery are given in the works on Toxicology, and to these, and in particular to the excellent treatise of Dr. Christison, the reader is referred.

B. Analysis of animal solids.

Solid matters, as tumours, concretions, and sediments, are best subjected to a preliminary test by the action of heat; the sediments are separated by filtration from the liquids in which they are deposited; by ignition on platinum foil of a few small fragments we observe either,

1. It is wholly or almost wholly dissipated, in which case it consists of,

Cholesterin, which fuses and burns with flame;

Uric acid, or *Urate ammonia*, } which are gradually dissipated, producing transient blackening of the foil around;

Cystic oxide, which is consumed with a peculiar odour;

Albumen, *fibrin*, or *hairs*, which swell up and burn with flame:

2. Or it blackens, leaving a less bulky residue;

In which case it may be

Urate of soda, *potash*, *Lime*, or *magnesia*, } they leave an alkaline ash, which in the two first fuses at a red heat, or it may arise from a mixture of some of the preceding list with some of those that follow.

3. Or, lastly, it undergoes little or no change in bulk, when it is composed of

Phosphates of the earths;

Carbonate of lime, or *magnesia;*

Oxalate of lime, which generally decrepitates.

Having by these simple trials acquired some knowledge of the nature of the substance we have to deal with, we proceed to a more special examination.

a. *Cholesterin* is the principal constituent of biliary calculi in the human subject, mixed with variable proportions of colouring matter. These calculi, when numerous, generally present facettes more or less flattened and polished; when solitary, they often attain considerable bulk, and are usually crystalline and semitransparent on the surface. Before the blowpipe they fuse and burn with a bright smoky flame, leaving but little ash. Boiling alcohol dissolves the cholesterin, and on cooling deposits the greater part in pearly glistening scales. Caustic potash dissolves the colouring matter and leaves the cholesterin. This last reaction distinguishes it from other fats, and particularly from lithofellic acid, recently discovered as an occasional constituent of bezoars and of gall-stones in the inferior animals; the lithofellic acid fuses at a higher temperature than cholesterin, and separates from its alkaline solution as an insoluble fat on neutralizing by a stronger acid.

b. *Uric acid* generally assumes the form of a reddish-brown crystalline sand, or of lighter-coloured rounded masses. Before the blowpipe it blackens and burns away, leaving only a minute trace of ash, usually alkaline, owing to the presence of a very small quantity of lime or soda. The manner of applying nitric acid, so as to produce the characteristic colour from the decomposition of uric acid, has been already mentioned. When powdered it dissolves completely in solution of potash by the aid of heat, and if the solution be supersaturated with hydrochloric acid, uric acid again precipitates in minute white crystals.

The urates are much more soluble in hot water than uncombined uric acid: they form amorphous deposits usually of a light brown colour.

Urate of ammonia before the blowpipe presents phenomena resembling uric acid; when rubbed with solution of caustic potash, ammoniacal fumes are emitted. In its other reactions, except that it is more soluble in boiling water, it closely resembles uric acid.

Urate of soda is distinguished by the large proportion of fusible alkaline ash left on ignition after the application of a red heat; the residue dissolves with effervescence in hydrochloric acid and gives no precipitate when this solution is treated with an alcoholic solution of chloride of platinum. If *potash* were present, it would be indicated by the formation of crystals on adding this test.

Urate of lime occasionally accompanies uric acid; the residue by incineration then yields the usual reactions of lime, such as a precipitate with oxalate of ammonia when added to a solution of the ash in acetic acid.

c. *Cystic oxide* is wholly dissipated by heat, emitting a peculiar odour. It is soluble readily both in acids and alkalies, and is deposited in hexagonal plates by spontaneous evaporation of its ammoniacal solution. The peculiar form of its crystal is at once recognized by the employment of the microscope.

d. *Albumen and fibrin* are discovered by their solubility in diluted alkalies and in acetic acid. Neutralization causes a flocculent precipitate soluble in excess of acetic acid or of the alkalies; the acetic solution gives a precipitate on adding ferrocyanide of potassium. Before the blowpipe they swell up, leaving a bulky coal which burns with difficulty to a small white or yellowish ash; they always contain saline matter. Albumen and fibrin, in common with all the compounds of protein, are further characterized by dissolving slowly in the concentrated acids; with *sulphuric acid* a crimson liquid is obtained, with *nitric* a yellow solution attended with effervescence during the action, and with *hydrochloric acid* a characteristic violet-coloured liquid is procured.

e. The *gelatinous tissues* may be shewn to be such by continued boiling in water for twenty-four or forty-eight hours; the liquid, if not too dilute, has then the property of gelatinizing on cooling; with infusion of galls it should produce an abundant flocculent buff-coloured precipitate.

f. Sometimes we meet with concretions formed principally of *hairs;* their texture and appearance generally betray their composition. Before the blowpipe they are dissipated with the well-known smell of burnt feathers. Solution of potash dissolves them slowly, and the liquid then gives the reactions furnished by alkaline solutions of albumen.

g. *Earthy phosphates*.—Phosphate of *lime* rarely occurs alone, either as a sediment or calculus; though in combination with others it is one of the most usual constituents of morbid concretions. Before the blowpipe, unless mixed with animal matters, it undergoes little change; usually a transient blackening appears from the charring of a little organic matter always present; by continuing the heat it becomes white. Nitric acid dissolves it readily, and phosphoric acid may be shewn by adding acetate of lead as directed when speaking of the detection of phosphoric acid. Ammonia in excess added to the acid solution causes a bulky gelatinous precipitate of bone earth; on redissolving in acetic acid, and adding oxalate of ammonia, we obtain abundance of oxalate of lime.

Phosphate of ammonia and magnesia, or, as it is frequently termed, *triple phosphate*, is a common constituent of calculi and of white sand; when in the form of a sediment it generally occurs in hemihedral six-sided prisms; heated before the blowpipe it emits ammonia, agglutinates, but is almost infusible; the addition of a fourth or a sixth of its bulk of phosphate of lime, as a shaving of bone or ivory, causes its immediate fusion to a white enamel-like bead. It is soluble in acids, and ammonia causes a crystalline precipitate of unchanged phosphate; phosphoric acid may be discovered by acetate of lead as before; oxalate of ammonia causes no precipitate in the acetic solution unless lime be present.

Not unfrequently these two kinds are mixed, constituting what has been termed the *fusible calculus*, from its property of forming the enamel-like bead before the blowpipe just mentioned. Heated with potash it evolves ammonia. Phosphoric acid and lime may be shown as before. After the separation of lime by oxalate of ammonia, supersaturation with ammonia throws down the crystalline phosphate of ammonia and magnesia.

h. *Carbonate of lime*.—These calculi before the blowpipe are converted into caustic lime, and then give a brown stain to turmeric paper. In dilute nitric or hydrochloric acid they dissolve with effervescence. Lime may be shown in the solution by appropriate tests.

i. *Oxalate of lime* is now and then met with, forming a gravel crystallized in pale amber-coloured prisms, but usually in the form of larger concretions, from their tuberculated exterior termed mulberry calculi; for the most part they have a dark brown or mahogany colour. Heated moderately before the blowpipe they yield a white ash, consisting principally of carbonate of lime, and dissolving with effervescence in acids. If the heat be greater, quicklime alone remains. It stains turmeric paper brown when moistened. Lime may be detected in the ash by the usual reagents. Oxalate of lime, when powdered, dissolves in nitric acid readily, more sparingly in hydrochloric acid. Ammonia throws it down unchanged from these solutions, and the precipitate is insoluble in acetic acid.

The whole of the preceding experiments may be made upon portions of matter not exceeding two grains, and most upon a quantity much smaller, especially if our examinations be aided by the microscope. Examinations of these matters are rarely quantitative; the small quantity of material procurable, and an unwillingness to sacrifice morbid products of this description for the purposes of analysis, prevent us from possessing information so full and detailed upon the constituents of concretions in general as the numerous collections in existence would have led us to expect.

Calculi, especially urinary calculi, are far from presenting a uniform and homogeneous structure throughout, being in many if not in most cases composed of laminæ differing materially in composition. It would be of little value to the pathologist to know the components of all the different layers mingled indiscriminately; the information he would derive as to the process by which the stone was formed, and of the means by which tendencies to such formations might be counteracted, would be of the most confused and indefinite description, tending rather to mislead than to aid him in forming correct conclusions. Just so it is when chemical analysis is applied to organized textures in general without due regard to the structure and disposition of the proximate elements within them; and hence the confused medley of substances obtained by subjecting them *as a whole* to the action of chemical agents. The texture, however, once known, and the action of our reagents upon it being watched under the field of the microscope, we can at pleasure separate the different ingredients, and obtain, with comparatively little difficulty, results which are fixed and producible at will; results which strictly belong to the domain of science, to whose enlargement and successful cultivation they then really contribute.

When soft tumours or malignant growths are submitted to our examination, one portion must as usual be carefully desiccated, to determine the proportion of moisture; and another, after being shred finely, macerated for some hours with water at a temperature not exceeding 100° F.; in this way the soluble albumen will be separated from the fibrous and other insoluble matters. The analysis must afterwards be proceeded with upon the principles already laid down, being first directed to the soluble ingredients and then to the insoluble matters.

C. Proximate analysis of individual secretions.

1. *Of the urine.*

The following is a detailed example of the method of analysing healthy urine:—

As there was abundance of the fluid for examination, fresh portions were taken whenever it seemed desirable to do so for determining any particular ingredient.

The secretion had a sp. gr. of 1020.4. It distinctly reddened litmus paper, and exhibited a slight cloud of floating mucus.

(*a*) 3200 grs. were filtered through a weighed filter, and the mucus collected. It amounted to 0.53 grs.

3200 : 1000 : : 0.53 : x (= 0.165) *mucus.*

(*b*) 200 grs. evaporated in a counterpoised capsule left 8.64 grs.

200 : 1000 : : 8.64 : x (= 43.2) *solid matters.*

1000 — 43.2 = 956.8 *water.*

(*c*) The residue, 8.64 after evaporation, ignited in the capsule left 2.36 grs. of saline matter.

200 : 1000 : : 2.36 : x (= 11.8) *fixed salts.*

(*d*) 1000 grs. of urine (freed from mucus by filtration) was evaporated to dryness in a platinum capsule. It was treated with water, acidulated with hydrochloric acid, and left 0.37 grs. of *uric acid;* after incineration of the uric acid a trace of *silica* remained.

(*e*) During the last three years I have made many careful analyses of the urine with express attempts to obtain from it the *lactic acid* it is said to contain; but though I employed various methods, and in some instances large quantities of urine, I have never succeeded in eliminating it from fresh urine, and I therefore (as the methods used were capable of detecting small quantities of the lactates when purposely mingled with the urine) concluded that lactic acid is not a normal constituent of human urine. Liebig has lately stated the same fact founded on his own recent examinations of the secretion.

(*f*) 1000 grs. of urine were evaporated to dryness and exhausted with alcohol. This alcoholic solution was evaporated, the dry mass treated with water, and nitric acid added, with the precautions already mentioned, furnished 29.17 grs. of nitrate of urea.

100 : 29.17 : : 48.78 : x (= 14.23) *urea.*

(*g*) The residue after exhaustion with alcohol weighed 6.6 grs. It was ignited, and left a saline mass, amounting to 4.46 grs.

6.6—4.46 = 2.14 organic matter.

From this we deduct the uric acid 0.37 (*d*), and mucus 0.165 (*a*), the residue 1.605, is "*watery extract.*"

(*h*) The portion soluble in alcohol amounts to 43.2—6.6, or 36.6 grs., which we find composed as follows:

The total saline matter of the urine (including the sulphuric acid volatilized by ignition (*r*))

amounts to . .	13.388 grs.	(= 11.8 + 1.588)
deduct	4.46	salts insoluble in alcohol (*g*)
remain	8.928	salts dissolved by alcohol.
fixed salts	8.928	
urea	14.230	by (*f*)
mur. ammonia	0.915	by (*v*)
	24.073	
36.6—24.073=	12.527	alcoholic extract.

The composition of the urinary salts has now to be determined.

(*i*) 1000 grs. of urine were acidulated with nitric acid, and mixed with a solution of nitrate of silver, an abundant precipitate of chloride of silver ensued.

The filter with the precipitate weighed	39.13
The filter alone	15.23
Total wt. of the chloride before fusion	23.90

23.12 of chloride fused in a counterpoised porcelain capsule gave 19.12 grs., weight of chloride after fusion.

23.12 : 23.90 : : 19.12 : x (= 19.77) fused chloride silver.

100 : 19.77 : : 25 : x (= 4.942) *chlorine.*

(*k*) The filtered liquid was treated with nitrate of baryta, the precipitate collected, well washed with boiling water, ignited, weighed 4.97 grs.

100 : 4.97 : : 34.19 : x (= 1.702) *sulphuric acid.*

(*l*) 1000 grs. of urine were supersaturated with ammonia; a bulky precipitate of the *earthy phosphates* fell, which after ignition weighed 0.65 grs.

(*m*) The filtered liquid supersaturated with lime-water gave a precipitate, which weighed after ignition 3.57 grs.

100 : 3.57 : : 49.1 : x (= 1.753) *phosphoric acid,* which is in combination with alkaline bases.

To determine the bases a considerable portion of urine was evaporated, and the residue burned to whiteness.

(*n*) 41.5 grs. of the saline residuum left 2.45 grs. insoluble in water.

41.5 — 2.45 = 39.05 alkaline salts.

41.5 : 11.8 (c) : : 2.45 : 0.6956 *insoluble salts in* 1000 *urine;* by (*l*) we found the earthy phosphates 0.65.

11.8 — 0.7 = 11.1 *alkaline salts* per 1000 urine.

(*o*) The insoluble portion dissolved in a little nitric acid, supersaturated with ammonia and redissolved in acetic acid, gave by oxalate of ammonia a precipitate which yielded on ignition 1.32 grs. carbonate of lime.

2.45 : 0.6956 : : 1.32 : x (= 0.3753) carb. lime.

100 : 0.3753 : : 56 : x (= 0.2101) *lime.*

(*p*) The solution filtered from the oxalate of lime and supersaturated by ammonia gave, on agitation followed by repose for some hours, a crystalline precipitate, weighing 1.18 grs. after ignition.

2.45 : 0.6956 : : 1.18 : x (= 0.3345)
100 : 0.3345 : : 35.71 : x (=0.1198) *magnesia.*

(q) 0.6956 — (0.2101 + 0.1198) = 0.3659 phosphoric acid with the earths.

0.3659 + 1.753 (m) = 2.1189 *total phosphoric acid in* 1000.

(r) 15 grs. of the alkaline salts (n) were dissolved in water and converted into chlorides by admixture with chloride of barium in excess; a precipitate of 6.4 grs. of sulphate and phosphate of baryta formed; on treating this precipitate with nitric acid, 0.45 sulphate of baryta remained.

15 : 11.1 (n) : 0.45 : 0.333.
100 : 0.333 : : 34.19 : 0.114 *sulphuric acid in the ash*, from 1000 parts of urine.

But 1000 grs. of urine we found (by k) to contain 1.702 grs. sulphuric acid, therefore 1.702 — 0.114 = 1.588 grs. of sulphuric acid have been expelled by ignition.

(s) The filtered solution was heated with caustic and carbonated ammonia to precipitate the excess of baryta as carbonate. The whole filtered, evaporated to dryness, and ignited to expel the ammoniacal salts. The fixed chlorides weighed 14 grs. They were dissolved in water, treated with bichloride of platinum, evaporated nearly to dryness by a water-bath, then treated with alcohol, the platino-chloride of potassium amounted to 13.40 grs.

15 : 11.1 : : 13.40 : 9.916.
100 : 9.916 : 19.43 : : x (= 1.926) *potash.*

(t) But 247, (1 eqt. platino-chlor. potassium) : 13.40 : : 76, (1 eqt. chlor. potassium) : x (= 4.123) chloride potassium, and 14 — 4.123 = 9.877 chloride sodium.

15 : 11.1 : : 9.877 : x (= 7.3089) chloride sodium,

and 60, (1 eqt. chlor. sodium) : 7.3089 : : 24 (1 eqt. sodium) : x (= 2.9235) *sodium.*

(u) 10 grs. of the alkaline salts were dissolved in water, the solution acidulated with nitric acid, and nitrate of silver added in slight excess: the precipitate of chloride of silver amounted to 15.61 grs.

10 : 11.1 : : 15.61 : x (= 17.3271)
100 : 17.3271 : : 25 : x (= 4.3317) *chlorine in the ashes* of 1000 parts of urine.

We find the equivalent quantity of sodium as follows:—

36 : 4.3317 : : 24 : x (= 2.8878) sodium, equivalent to the chlorine.

The *chloride of sodium* therefore amounts to 7.2195 grs.; deducting the sodium combined with chlorine from the entire quantity in the urine (t), we obtain

2.92356 — 2.8878 = 0.03576, or 0.0536 *soda.*

(v) Now before ignition the chlorine (by i) amounted to 4.942 grs.

deduct.... 4.3317 combined with sodium in the ash.

0.6103 chlorine volatilized, probably in the form of muriate of ammonia, the amount of which appears by the following calculation:

36 : 0.6103 : : 54 : x (= 0.9154) *muriate ammonia.*

The results of the analysis are here subjoined.

Water			956.8000
*Organic matters & ammoniacal salts	29.8224	Urea	14.2300
		Uric acid	0.3700
		Alcoholic ext.	12.5270
		Watery ext.	1.6050
		Vesical mucus	0.1650
		Mur. ammonia	0.9154
Fixed saline matters	13.1494	Chlor. sodium	7.2195
		Phosphc. acid	2.1189
		Sulphuric acid	1.7020
		Lime	0.2101
		Magnesia	0.1198
		Potash	1.9260
		Soda	0.0536
			999.9623

In analysing *diabetic urine* the method must be modified, as will be seen by the following example.

It was feebly acid, and had a specific gravity of 1038.

Evaporated in vacuo over sulphuric acid, it furnished a pale amber-coloured soft mass, which weighed,

On the third day....	55.9 grs.
sixth	54.1
ninth	53.4
fourteenth ...	53.1
thirtieth.....	52.2

The temperature varied between 60° and 70°, and the vacuum shewed from 1 inch to 1½ inches on the pressure gauge.

The presence of even a very small portion of air materially retards the progress of the evaporation.

From the weight on the thirtieth day we find

500 : 1000 : : 52.2 : x (= 104.4) *solid contents*, and
1000—104.4 = 895.6 *water.*

As a contrast to this evaporation in vacuo, the remainder from 500 grs. was evaporated by water-bath, the temperature never rising above 180° F.

In 24 hours the residue weighed	48.4 grs.
48	46.9
72	46.1
96	46.0

By this time it had assumed a deep brown colour, and from being soft and sectile had, with the exception of a small portion in the centre, become hard and brittle; by exposure to the air it speedily deliquesced; 30.6 grs. of the dry mass dissolved in water was mixed with 16.7 grs. of yeast, which from the evaporation of another portion was found to contain 3.5 grs. of solid matter. The mixture was set aside for four days at a temperature of 70° to ferment; gas was slowly disengaged; when fresh bubbles ceased to form, the solution was evaporated to dryness, and amounted to 25.8 grs.; deducting 3.5 solid matters of the yeast, we have an unfermentable mass of

* The sulphuric acid has been deducted from the amount of organic matter determined by b and c, and added to that of the saline matters.

22.3 grs. out of 30.6, shewing the quantity of sugar to have amounted to only 8.3 grs., instead of about 24.5 grs. The foregoing experiment shews the impossibility of obtaining an accurate result if the solution be evaporated in air even at temperatures considerably below 200°. Diabetic sugar, in fact, loses by this treatment 5 equivalents of water, and becomes converted into a species of caramel, insusceptible of fermentation.

To proceed, however, with the analysis:

The salts were found by incineration to amount to 3.09 per 1000 parts of urine.

To determine the quantity of sugar, 250 grs. of the secretion were mixed with yeast and placed in a tall graduated jar capable of containing 25 cubic inches; filled with mercury, and inverted in a basin holding that metal,

The barometer stood at 30.33
The thermometer .... 72° F.
Air in the jar, which accidentally entered during the act of inversion 1.00 cub. in.
Quantity of fluid........... 1.45 cub. in.
Exterior level of the mercury 12.33 inches below the interior level.

In three days fermentation was complete.
The barometer then stood at.... 30.34
The thermometer............. 80°
Exterior level of the mercury 1.14 below that of the interior.

The quantity of gas amounted to 19.3 cub.in.
adding the bulk of the fluid ... 1.45

We obtain total gas.......... 20.75

Correcting for pressure we obtain
30 : 30.34 — 1.14 : : 20.75 : x (= 20.1828)
Correcting this again for the temperature,
528 : 508 : : 20.1828 : x (= 19.41)

Subjecting the air which was in the jar at the commencement of the experiment to the same corrections, in order to deduct, we obtain

For the temperature
520 : 508 : : 1 : x (= 0.9769)
For the pressure
30 : 30.33—12.33 : : 0.9769 : x (= 0.586)
19.41—0.58 = 18 83 corrected volume of carbonic acid.
Now 100 : 18.83 : : 106.6 : x (= 20.072) total number of grs. of sugar in 250 grs. of urine, and
250 : 1000 : : 20.072 : x (= 80.29) *sugar.*

The urea was found by a separate analysis; 500 grs. were evaporated in vacuo, the residue treated with hot *absolute* alcohol (f.℥ß). It was allowed to cool in order to deposit part of the sugar, then decanted; this was repeated three or four times. The alcoholic solutions were evaporated to dryness, re-dissolved in water, and treated with oxalic acid and subsequently with chalk, observing the precautions already enumerated: 1.06 grs. of prismatic needles of nearly pure urea were obtained.

500 : 1000 : : 1.06 : x (= 2.12) *urea.*

As a comparative experiment 500 grs. were evaporated by the water-bath and nitric acid substituted for the oxalic; only traces of crystals of nitrate of urea were thus obtained; a conclusive proof of the superior delicacy of the first method.

The syrupy residue after exhaustion with absolute alcohol was treated with rectified spirit as long as any thing dissolved: 2.15 grs. of saline matters, uric acid, mucus, and matters soluble in water only were left. Hydrochloric acid left only 0.04 of uric acid and mucus.

500 : 1000 : : 0.04 : x (= 0.08) *uric acid, &c.*

The acid solution evaporated to dryness and incinerated, gave 0.69 grs.

500 : 1000 : : 0·69 : x (= 1.38) *salts insoluble in alcohol.*
2.15 — (0.04 + 0.69) = 1.42.
500 : 1000 : : 1.42 : x (= 2.84) *watery extract.*
By calculation, as in the previous analysis, the *alcoholic extract* is 15.98 grs.

The composition of the urine is thus determined to be

Water		....	895.60
Fixed salts		....	3.09
Organic matters & volatile salts	101.31	Sugar	80.29
		Urea	2.12
		Alcoholic extr.	15.98
		Watery extract	2.84
		Uric acid & muc.	0.08
			1000.00

Where *albumen* occurs in the urine, we porceed as in the following instance.

The fluid was rather turbid, feebly alkaline, and of sp. gr. 1013.1. It was found to contain 30.2 per 1000 of solid matter, of which 9.17 were salts and 21.03 organic volatile matters.

500 grs. evaporated to dryness, and the residue finely powdered, taking care that none of the particles were lost (by placing the mortar on a large sheet of paper, and covering the mouth of it likewise with paper). It was treated with boiling water and washed as long as any thing dissolved. The insoluble portion collected on a filter, dried and weighed, amounted to 3.1 grs.

500 : 1000 : : 3.1 : x (= 6.2) *albumen*, with traces of *uric acid.*

The filtered liquid was evaporated to dryness, and treated with alcohol and nitric acid for urea in the usual manner: *the urea per* 1000 = 4.72 grs.

The other ingredients were determined as usual and furnished the following results.

Water		....	969.80
Saline matters		....	9.17
Organic matters	21.03	Albumen and uric acid ..	6.20
		Urea	4.72
		Alcoholic extract	8.43
		Watery extract..	1.68
			1000.00

2. *Analysis of the blood.*

Unless present when the blood is drawn, we are obliged to proceed as in the following example, furnished from a patient suffering from a chronic cerebral affection.

(*a*) The entire blood employed amounted to 6735 grs.; it had been drawn 24 hours, and had formed a tolerably firm but flat coagulum, which weighed 3560 grs. The serum that had separated weighed 3175 grs., and had a sp. gr. of 1029.3.

The proportions of clot and serum were therefore as follows, in 1000 parts.

6735 : 1000 : : 3560 : x (=528.6) *coagulum.*

6735 : 1000 : : 3175 : x (= 471.4) *serum.*

The analysis divides itself into two portions, that of the serum, and that of the clot.

Analysis of the serum.

(*b*) 200 grs. of serum were dried at a temperature of 212°. The residue amounted to 18.69 grs.

200 : 1000 : : 18.69 : x (= 93.45) *solids in serum.*

Therefore 1000 — 93.45 = 906.55, *water in the serum.*

(*c*) The residue was incinerated over the circular wicked spirit lamp, and amounted to 1.46 grs.

200 : 1000 :: 1.46 : x (= 7.3) *saline matters.*

(*d*) 500 grains of serum were dried in a platinum capsule, the dry mass carefully detached, pulverized, and digested in boiling ether, which was decanted and renewed three or four times. The ethereal solutions evaporated left 0.35 grs. of fatty matter; of this cold alcohol dissolved 0.12 oily fat, leaving 0.23 of crystalline fats.

1000 parts of serum therefore contain 0.24 *oily fat*, and 0.46 *crystalline fats.*

(*e*) The undissolved residue was heated to expel adhering ether and treated with boiling water. It was thrown on a filter and washed repeatedly, until nitrate of silver produced an insignificant cloud when applied to a few drops of the washings. The filter and its contents were dried; when weighed the albumen amounted to 41.73 grs.

10 grs. when incinerated yielded 0.19 grs. of ash; 10 : 41.73 : : 0.19 : x (= 0.79287.)

41.73 — 0.793 = 40.937; 40.937 × 2 = 81.974 *albumen.*

(*f*) The filtered liquid evaporated weighed 4.66 grs. It was digested with alcohol, which was renewed as long as any thing was dissolved. The alcoholic solution evaporated amounted to 3.32 grs. (If urea, sugar, or bile be present, they will be contained in this extract and must be sought for in the usual manner.)

4.66 — 3.32 = 1.34 grs. watery extract, 1.34 × 2 = 2.68. 1 gr. of watery extract incinerated left 0.82 grs. of salts, and 1. : 2.68 : 0.82 : x = 2.197, and 2.68 — 2.197 = 0.483 *watery extract* per 1000.

(*g*) 1.4 grs. of alcoholic extract, incinerated, left 1.00 grs. of saline matter.

Now 1.4 : 1 : : 6.64 : x (= 4.74) saline matters,

And 6.64 — 4.74 = 1.90 *alcoholic extract* per 1000.

The serum therefore consists of

Water	906.550
Fixed salts	7.300
Albumen	81.974
Alcoholic extract	1.900
Watery extract	0.483
Fats, oily	0.240
„ crystalline	0.460
	998.907

Analysis of the clot.

(*h*) 1000 grs. shred finely with a sharp knife were tied in a piece of calico and washed till colourless under a gentle stream of water. The fibrin that remained carefully dried at 212° weighed 5.67 grs.

Ether dissolved from this 0.07 grs. of oily fat.

The pure fibrin therefore amounted to 5.60 grs.

1000 : 528.6 : : 5.6 : x (= 2.962) *fibrin.*

1000 : 528.6 by (*a*) : : 0.07 : x (= 0.04) *fat from fibrin.*

(*i*) 500 grs. of the coagulum completely dried at 212° left a residue of 143.6 grs.

500 : 528.6 : : 143.6 : x (= 151.81) solids in the clot.

(*k*) 528.6 — 151.8 = 376.8 water in the clot.

Supposing the water entirely due to the serum with which the clot is penetrated, we should find it contain—

Since by (*b*) 906.55 : 376.8 : : 93.45 : x (= 38.86) solids of the serum retained by the clot, and

376.8 + 38.86 = 415.66 weight of the serum retained.

But 415.66 + 471.4 by (*a*) = 887.06 total serum in 1000 parts of blood.

(*l*) 20 grs. of the dried matter of the coagulum ignited left a red ash, weighing 0.52 grs.

20 : 151.81 : : 0.52 : x (= 3.947) salts in the clot.

But 1000 : 471.4 : : 7.3 by (*c*) : x (= 3.441) salts in the exuded serum.

3.947 + 3.441 = 7.388 *salts in* 1000 *parts of blood.*

(*m*) Since the coagulum contains 2.962 fibrin,
And the serum retained ...... 38.860 solids.

The sum of the two = 41,822

And by deducting this sum from the total solids contained in the clot we find

151.81 — 41.822 = 109.988 *red particles in* 1000 *of blood.*

(*n*) In order therefore to deduce the composition of 1000 parts of blood, we have only to calculate the following proportions from our knowledge of the composition of the serum.

1000 : 887.06 : : 906.55 : x (= 804.164) *water.*

1000 : 887.06 : : 81.974 : x (= 72.716) *albumen.*

1000 : 887.06 : : 1.900 : x (= 1.685) *alcoholic extract.*

1000 : 887.06 : : 0.483 : x (= 0.428) *watery extract.*

1000 : 887.06 : : 0.24 : x (= 0.213) oily fat.

To this we must add 0.04 from the fibrin, making the *total oily fat* = 0.253.

1000 : 887.06 : : 0.46 : x (= 0.408) *crystalline fat.*

1000 parts of this blood therefore consist of

Water		804.164
Fixed salts		7.388
Organic matters, 188.440.	Red particles	109.988
	Albumen	72.716
	Fibrin	2.962
	Alcoholic extract	1.685
	Watery extract	0.428
	Oily fat	0.253
	Crystalline fat	0.408
		999.992

3. *Analysis of milk.*

Occasionally we may have to perform an analysis of milk: we may proceed as in the following instance.

The milk was rather thin, watery in appearance, and had a sp. gr. of 1031. It was obtained from a woman aged 25, three weeks after the birth of her fourth child.

(*a*) 100 grs. evaporated to dryness left 11.49 grs. of solid matter.

100 : 1000 : 11.49 : x (= 114.9) *solids per* 1000.

1000 — 114.9 = 885.1 *water per* 1000.

(*b*) On incinerating the residue, an alkaline ash was left amounting to 0.24 grs. = *salts* 2.4 *per* 1000.

(*c*) 158 grs. of the milk were mixed with a few drops of acetic acid and evaporated to dryness, and digested repeatedly in ether (the ether was first allowed to macerate upon the residue unpowdered. It was decanted and the greater part of the fat thus removed; the residue was completely dried, powdered, and again subjected to three or four digestions with ether. All the ethereal solutions were then evaporated.) The fatty matter amounted to 4.61 grs.

158 : 1000 : : 4.61 : x (= 29.13) *butter per* 1000.

(*d*) The portion insoluble in ether was digested in dilute alcohol (sp. gr. 920) as long as any thing dissolved. The solution on evaporation yielded a yellowish granular mass, consisting of milk sugar, and a little extractive matter: it amounted to 9.7 grs. and appeared perfectly free from casein.

158 : 1000 : : 9.7 : x (= 61.39) *sugar of milk per* 1000.

(*e*) The insoluble residue consisted almost entirely of casein, with a small quantity of saline matter. Calculating by the deficiency, (as, owing to an accident, it was not weighed,) it amounted to 3.85 grs.

158 : 1000 : : 3.85 : x (= 24.37) *casein per* 1000.

The results of the analysis may be summed up as follows:—

Water		885.1
Organic matter, 112.5. Saline residue, 2.4.	Fatty matter	29.13
	Sugar and alcoholic extract	61.39
	Casein and watery extract	24.38
		1000.00

The proportion of "extractive matter" in milk varies, but I am not aware of any ready method of determining its quantity, apart from that of the sugar and casein. If we attempt to digest casein in water, it swells up and partly dissolves, becomes gelatinous, and does not allow the fluid to pass through the pores of the filter. If a cold saturated solution of sugar of milk in proof spirit, (sp. gr. 920,) be allowed to digest for a few days in a closed flask upon the spirituous extract (*d*), the liquid assumes a yellow colour from dissolved extract, and the sugar is left in white crystalline grains, but this can hardly be used as a process for analysis.

4. *Analysis of bile.*

Our methods for analysing this complicated and important secretion are very inadequate. Still, such as they are, I have endeavoured to illustrate them by the following example:—

The bile analysed was obtained from a man æt. 75, who died of gangrena senilis. The gall-bladder was removed entire, and the bile examined 48 hours after death.

It was a brownish, turbid, scarcely ropy fluid, of sp. gr. 1024, and amounted to about 240 grs.

(*a*) 65.16 grs. evaporated to dryness left 4.83 grs. This residue on incineration left 0.75 grs. of saline matter.

65.16 : 1000 : : 0.75 : x (= 11.51) *salts per* 1000.

4.83 — 0.75 = 4.08 and

65.16 : 1000 : : 4.08 : x (= 62.61) *organic matter per* 1000.

Therefore 1000—(11.51 + 62.61) = 925.88 *water per* 1000.

(*b*) 171.2 grs. mingled with thrice its bulk of alcohol, and filtered, left a yellowish ropy residue of mucus, which, when well washed with alcohol and dried, amounted to 5.1 grs.

171.2 : 1000 : : 5.1 : x (= 29.78) *mucus per* 1000.*

(*c*) The filtered liquid was evaporated nearly to dryness and mingled with ether. A bright yellow solution was obtained; it was decanted, and the residue repeatedly digested with ether. The mixed ethereal solutions, on evaporation, left 2.8 grs., of which 0.6 grs. was soluble in water (being biliary matter).

2.8 — 0.6 = 2.2 ethereal extract.

(*d*) The ethereal extract was treated with a weak solution of ammonia; a brown liquid was obtained, and a white crystalline residue of cholesterin was left, amounting to 0.31 grs.

171.2 : 1000 : : 0.31 : x (= 1.81) *cholesterin per* 1000

2.2 — 0.31 = 1.89.

171.2 : 1000 : : 1.89 : x (= 11.04) *uncombined fatty and resinous acids per* 1000.

(*e*) The residue insoluble in ether was treated repeatedly with hot alcohol. It left undissolved a remainder, which when dry amounted to 2.92 grs.

171.2 : 1000 : : 2.92 : x (= 17.05) *watery extract.*

* The proportion of matter insoluble in alcohol in this instance was very great, probably it contained something besides ordinary mucus; but circumstances prevented my examining it more minutely.

(*f*) An attempt was made to separate the colouring matter from the alcoholic extract by baryta water, and to obtain it free from baryta by solution in carbonate of ammonia, but it did not succeed; indeed I have never been able by this or any other process to separate the colouring matter from the other ingredients of the bile with sufficient accuracy to warrant its adoption for analytical purposes.

(*g*) The quantity of alcoholic extract was in this case from the experiment with the baryta necessarily inferred from the deficiency.

Since 1000 grs. contain 74.12 of solid matters, 171.2 grs. will contain 12.69; we must, therefore, deduct the ethereal and watery extract, and mucus:—

$(2.2 + 2.92 + 5.1) = 10.22$ grs.

$12.69 - 10.22 = 2.47$. Biliary and colouring matter:—

171.2 : 1000 : : 2.47 : x (= 14.37) *biliary matter per* 1000.

The specimen of bile thus examined, therefore, furnishes the following results:—

Water		925.88
Organic matter, 62.61. Fixed salts, 11.51.	Mucus	29.78
	Biliary and colouring matter	14.37
	Resinous and fatty acids	11.04
	Cholesterin	1.81
	Watery extract	17.05
		999.93

M. Pettenkofer has recently proposed the change of colour produced by the action of sulphuric acid and sugar upon bile as a test of its presence. Having freed the liquid suspected to contain it from albumen by evaporating to dryness and exhausting the residue by boiling water, the solution is concentrated by evaporation, and when cold mingled with about one-third of its bulk of oil of vitriol, so as to raise the temperature of the mixture from 150° to 160° of Fahrenheit, but not higher. A few grains of sugar are now added to the liquid, and the whole suffered to stand for a few minutes. If bile be present a beautiful crimson colour is developed, increasing in intensity for some minutes. The tint is unequivocal provided the solution contain not less than $\frac{1}{200}$ of its weight of dry bile, or $\frac{1}{30}$ of the recent secretion. This reaction is independent of the mucus and colouring matter.

5. *Of the saliva.*

The saliva is not often the object of analysis; when it is, it may be proceeded with as in the following instance, in which healthy saliva was examined. It was obtained several hours after taking food. It had a sp. gr. of 1001.5, was slightly alkaline, restoring the colour of reddened litmus paper; and was ropy and opalescent.

(*a*) 111 grs. evaporated to dryness in a platinum capsule and incinerated, left 0.22 grs. of ash.

111 : 1000 : : 0.22 : x (= 1.98) *saline matter per* 1000.

(*b*) 500 grs. evaporated by a water-bath left 2.51 grs.

500 : 1000 : : 2.51 : x (= 5.02) total solids.

$5.02 - 1.98 = 3.04$ *organic matter.*

$1000 - 5.02 = 994.98$ total quantity of *water.*

(*c*) The dry residue was digested in ether; the ethereal solution decanted and evaporated left 0.03 grs. of an oily matter with a strong peculiar odour. It contained a trace of sulphocyanide of potassium, as was shewn by the red colour struck by a very dilute solution of sesquichloride of iron.

500 : 1000 : : 0.03 : x (= 0.06) *fatty odorous matter* with traces of sulphocyanide potassium.

(*d*) The residue undissolved by ether was treated with boiling alcohol; the solution decanted and evaporated left 0.61 of a crystalline yellowish deliquescent salt, in which the presence of sulphocyanide of potassium was proved; 1st, by its striking a blood-red liquid with a very dilute solution of sesquichloride of iron; and 2ndly, this solution, according to Dr. Percy's suggestion, was acidulated with hydrochloric acid, and a fragment of zinc dropped in. Immediate effervescence ensued with a strong odour of sulphuretted hydrogen due to the decomposition of the sulphocyanide. Its acidulated aqueous solution gave no precipitate with nitrate of baryta; but after a small portion of the alcoholic extract had been incinerated and the residue dissolved in water feebly acidulated with nitric acid, abundant precipitation was manifest on adding a solution of chloride of barium; during incineration the sulphocyanide had been decomposed and the sulphur, by absorbing oxygen, converted into sulphuric acid.

500 : 1000 : : 0.61 : x (= 1.22) *alcoholic extract.*

(*e*) The residue left undissolved by alcohol was treated with water and thrown upon a weighed filter; the insoluble portion amounted to 0.68: it consisted of mucus, debris of epithelium, &c.

500 : 1000 : : 0.68 : x (= 1.36) *mucus.*

(*f*) The filtered solution contained traces of albuminous matter (mucus) held in solution by the soda. This was precipitated by exact neutralization with acetic acid, evaporated to dryness, redissolved, and again filtered. This aqueous liquid contained the ptyalin, or peculiar salivary matter, and a certain proportion of watery extract so called. Ptyalin has never yet been obtained in a state of purity. It always contains chlorides and phosphates mixed with it. The solution was mixed with twice its bulk of alcohol, by which the ptyalin in company with some watery extract was precipitated. Its solution, when redissolved in water, gave precipitates with acetate and triacetate of lead, infusion of galls, and nitrate of silver, but none with corrosive sublimate, sesquichloride of iron, or ferrocyanide of potassium, either alone or after the addition of acetic acid. Each time it is evaporated to dryness a small portion remains behind in an insoluble form. Deducting the ethereal and alcoholic extract, and mucus,

$5.02 - (1.22 + 0.06 + 1.36\,(e)) = 2.38$ represents the *ptyalin and watery extract per* 1000.

This specimen of healthy saliva therefore contained,

Water		994.98

	Alcoholic extract and salts	1.22
	Mucus and epithelium	1.36
	Ptyalin, watery extract, salts and traces of mucus	2.38
		1000.00

If mercury were sought for, the best plan would be to mix a little nitric acid with the saliva, evaporate to dryness, mingle the dry mass with well-dried carbonate of soda, to place the mixture in a fine glass tube sealed at one end, and apply the heat of a spirit lamp. If the metal were there, it would sublime and condense as a dew of metallic globules on the cool part of the tube.

II.—Ultimate Analysis.

Organic bodies consist principally of carbon, hydrogen, oxygen, and nitrogen, with occasionally small quantities of sulphur, phosphorus, and various metallic, earthy, and saline matters in minute proportions. In cases where the four first elements only are present, the analysis is comparatively easy; and if, as sometimes occurs, the substance to be analysed is capable of assuming a crystalline form, its purification is a matter of little difficulty. When, however, saline compounds enter essentially into its constitution, as in most animal principles, crystallization is never found to take place.

This general absence of crystalline form in animal principles, and the consequent difficulty of ascertaining that they are free from all moisture, which does not chemically enter into their constitution, have, by rendering us uncertain of the purity of the substances analysed, mainly contributed to the slow and uncertain progress of this department of chemistry, and have given rise to the numerous contradictory statements with which it abounds. By multiplied researches and experiments we are, however, at length arriving at results on the accuracy of which tolerable confidence may be placed.

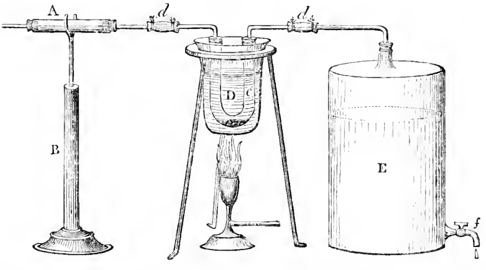
The determination of the four elements, carbon, hydrogen, oxygen, and nitrogen, as they constitute the bulk of most organic substances, is that part of the process which now claims our attention. It is to Gay Lussac and Thenard that we are indebted for the fundamental principle that regulates our operations. The process proposed by them has subsequently been modified and improved by many chemists, especially by Berzelius, Prout, and Liebig, and in the hands of the latter eminent philosopher it has acquired a degree of facility and accuracy hitherto unapproached in any other department of analytical research.

Our object being to determine the relative proportion in which each of the ultimate elements exists, it becomes necessary to the success of any analytical process that we should procure them in the form of definite compounds that can easily be collected; and it has been found most convenient, by supplying the substance to be analysed with a sufficient quantity of oxygen, to convert the carbon into carbonic acid, which may be absorbed by potassa and weighed, and the hydrogen into water, which may likewise, by passing over a substance that has a powerful attraction for it, such as chloride of calcium or sulphuric acid, be collected and weighed, whilst the nitrogen escapes as gas, which is collected over mercury and measured.

In cases where nitrogen is present, it has recently been proposed to heat the substance to be analysed along with hydrate of soda or potash; all the nitrogen is thus converted into ammonia, in which form, like carbonic acid and water, it admits of being weighed. By calculation it is easy to find the weight of the carbon, hydrogen, and nitrogen respectively contained in the carbonic acid, water, and ammonia collected. Carbonic acid contains three-elevenths of its weight of carbon; water, one-ninth of hydrogen, and ammonia fourteen-seventeenths of nitrogen. When by incineration of a portion of the mass the proportion of saline matter has been determined, the quantity of oxygen the substance contains may be known by deducting the united weight of the carbon, hydrogen, nitrogen, and salts from the total weight of the body analysed; the deficiency (supposing sulphur and phosphorus not to have been present) is oxygen.

Scrupulous attention to the purity of the matter submitted to analysis is of course of primary importance, a very slight admixture

Fig. 429.



Apparatus for desiccation of organic substances.

with other compounds being sufficient to vitiate the conclusions deducible from our experiments. Having ascertained the purity of our substance, the next care is to ensure its complete desiccation. For this purpose the following plan, recommended by Liebig, will be found the most efficient (*fig.* 429). A small quantity of the material to be dried is placed in an inverted syphon-tube (*c*), the bend of which is plunged into a vessel (D), containing water gradually heated to the boiling point. When plain water is used, the temperature of course will not rise above 212°; but by substituting for it different saline solutions we may at pleasure obtain any degree of heat between 212° and 300°, according to the nature of the compound to be analysed. A current of dry air is made to pass over the substance by connecting one limb of the syphon with a tube containing chloride of calcium (A), and the other with a vessel (E) closed at top, excepting the aperture by which it is connected with the syphon-tube, and filled with water, which is allowed to run out at the bottom with a speed regulated by a stop-cock (*f*), the place of the liquid being supplied by air, which has passed over the chloride of calcium and then through the syphon-tube. Volatile liquids that are unchanged by distillation should be allowed to stand two or three days upon fragments of fused chloride of calcium; the liquid should then be decanted and distilled in a small retort; in other cases, as in the examination of fats or fixed oils, it may be more convenient to dry the material in a watch-glass placed in an ordinary water-bath or the hot-water oven previously described. The further progress of the analysis will vary according to the form and composition of the substance to be examined.

We shall describe the methods of analysing—

1. A *solid*, which does not contain nitrogen.
2. A *fluid*, which does not contain nitrogen.
3. A substance, which *does contain nitrogen*.

1. *Analysis of a solid not containing nitrogen.*

The combustible which answers best in these experiments is charcoal; it is the least expensive, and very manageable, but dusty. Spirits of wine or pyroxylic spirit, no doubt, are cleaner, but their expense is a great objection. Gas has been tried by myself and others in a variety of ways, but though some modifications of burner answer tolerably well, it is not on the whole to be recommended.

The best furnace to be used with the charcoal is represented at A, *fig.* 430, and is made of stout sheet-iron bent into the form of a trough, open at one end; the plate which closes the other is perforated with an aperture three-quarters of an inch in diameter, to allow the passage of the combustion tube; the furnace is about twenty inches long, five inches at top, two inches and three-quarters at bottom, and three inches high. Transverse slits are made along the floor at intervals of two inches for draught, and between each are rivetted vertical stiff pieces of sheet-iron one inch high, terminating in a concave edge above, for the support of the combustion tube. The apparatus may rest on bricks during the operation, as represented in the wood-cut.

The tube in which the mixture is burned, *the combustion or retort tube*, (*fig.* 430, *a*, *b*, *c*,) should be of difficultly fusible glass free from lead, about fifteen inches long and half an inch in diameter: the hard Bohemian glass answers the purpose perfectly. The tube may on certain occasions be drawn out into a fine but strong tail bent upwards at an obtuse angle, and the mouth should be smoothed by making it red hot in the flame of the blowpipe, so that a cork need not be torn in adjusting it.

The apparatus for containing the chloride of calcium which collects the water, *or drying tube*, is conveniently made of the shape depicted (*fig.* 430, B): it consists of a tube about half an inch in diameter and four inches long. Upon one end is blown a bulb, to contain a larger portion of the chloride, and from the bulb a strong tube of small diameter extends for an inch and a half. The chloride of calcium with which it is filled must not be fused, but should be prepared merely by evaporating the solution of the chloride to dryness by a strong sand heat. A porous mass is thus obtained, which does not crystallize by absorbing moisture, as the fused variety does, to the destruction of the tube that contains it. In order to charge the apparatus a few fibres of cotton wool are put into the bulb, and by sucking air through the small end adjusted over the aperture of the fine tube to prevent any minute particles from falling out: into the apparatus to

D, the suction tube, shewing the mode of its adjustment when used for drawing air through the apparatus at the termination of the experiment.

within three-quarters of an inch of the large end, the chloride broken into fragments about the size of peas, is put, and a loose piece of cotton-wool, occupying another quarter of an inch, thrust in; the opening is then closed by a cork, through which passes a bit of straight tube, rather larger in the bore than that attached to the bulb, and projecting about an inch outside the whole; the cork is trimmed close to the large tube and covered neatly with melted sealing-wax; and, lastly, air is drawn through the apparatus by the mouth to ascertain that no obstruction exists. It is now ready for use: after two or three experiments the chloride should be renewed, or there will be a danger of the gases being imperfectly dried. The tube when not in use must always be placed in a rack with the bulb end uppermost to prevent the loss of any small pieces of chloride. Concentrated sulphuric acid may be advantageously substituted for chloride of calcium in the drying tube. In this case the tube is filled with fragments of pumice-stone; these are moistened with the oil of vitriol, and the apparatus is fitted up as usual, excepting that the employment of the cotton-wool is dispensed with.

The combustion tube is then prepared by selecting a sound elastic cork, which is made accurately to close the mouth of the tube; it is pierced with a round file, and fitted firmly upon the fine tube proceeding from the bulb of the drying tube; the cork is then well dried on the sand-bath, and forms the medium of connection between the retort and drying tube.

The potash apparatus is one invented by Liebig, represented in *fig.* 430, *e*. It consists of a fine but stout tube, upon which is a series of bulbs, three in the middle horizontal part of the instrument, and one on each of the ascending limbs; one of the latter bulbs is made considerably larger than the other; the apparatus is filled by adjusting a suction tube to one of the openings, and exhausting by the cheeks until a certain measured quantity of solution of potash has entered; when the liquid fills each of the three lower bulbs rather more than three-quarters of their capacity, sufficient has been introduced.

The solution of potash employed has a sp. gr. of from 1.25 to 1.27, and must be renewed for every experiment; the portions that have been used may be put aside, and afterwards, when sufficient has been collected, may again be rendered caustic in the usual way by quicklime.

The compound commonly used for supplying oxygen to the substance burned is oxide of copper, which readily imparts oxygen to combustible matter in contact with it, but bears a very high temperature *per se* without decomposition. It is best procured by dissolving copper in pure nitric acid, evaporating to dryness and decomposing the nitrate by heating it strongly in an earthen crucible. Ignition is kept up till red fumes cease to appear; if the heat be too great the oxide becomes agglutinated, and requires strong pounding in an iron mortar to pulverize it; it however, in this dense state, is much less hygroscopic, and therefore better adapted for the purposes of analysis. The powdered oxide is sifted through a fine copper sieve, and secured in stoppered glass bottles.

Immediately before each analytical operation a sufficient quantity of the oxide is ignited, and while still hot transferred to a dry tube, by plunging the mouth of the tube into the oxide in the crucible and then shaking it in piecemeal. The tube with the oxide is immediately closed with a dry cork, and allowed to cool. Meantime the interior of the retort is completely dried by heating each portion of it in succession in the flame of a spirit-lamp, beginning at the closed end, and drawing air through the heated tube, by means of a narrower tube passed down just beyond the heated part and exhausting by the mouth; when every part has thus been dried, the retort is corked and allowed to cool. Five or six grains of the powdered and dried substance are put into a perfectly dry test tube, and the whole is very accurately weighed; its contents are then added to the oxide of copper in the mortar and the empty tube again weighed; the difference gives the weight of the substance employed.

The best kind of mortar is one of Wedgewood ware or Berlin porcelain, capable of containing about half a pint, with a pestle composed of a single piece of the same material; it should be thoroughly dried and well warmed. Much caution is requisite in charging the retort. The warm dry mortar is placed on a sheet of glazed paper and first cleared out with a little of the dried oxide of copper, which is put aside. Oxide to the depth of an inch is poured into the combustion tube; a small quantity of oxide is put into the mortar, then the substance to be analysed, then more oxide; the mixture must be made quickly and carefully, adding so much oxide as shall be sufficient to fill a little more than half the retort; the mortar is then taken in the palm of the left hand and the mixture introduced, carefully picking it up piecemeal by the retort tube itself; fresh portions of oxide are rubbed in the mortar to clear out the last traces, and the retort is then filled up with pure oxide of copper to within two inches of the extremity.

The proportions of the mixture are represented in *fig.* 430: the portion from the tail of the tube to the letter *a* consists of pure oxide of copper, from *a* to *b* of the mixture, from *b* to *c* of the rinsings of the mortar, and from *c* to within an inch of the cork is again pure oxide.

If the process of mixing has occupied much time, it may be advisable to subject the tube and its contents to a further operation to remove any traces of moisture that may have been absorbed. The tube is struck smartly in a horizontal position on the table, to clear the tail-like prolongation, and to make an air-way above the oxide from end to end; an exhausting syringe made fast to the table by a screw-vice or other convenient means, is attached to a long tube filled with chloride of calcium; and this drying apparatus is fitted by a sound cork to the retort tube. This latter is laid in a shallow trough open at one end, which is slightly elevated; the trough is then filled with sand heated to about 212° F., and cautious exhaustion is performed by the syringe, taking care that none of the charge is carried out of the tube by the current of air; on gradually opening the stop-cock air is slowly re-admitted, being dried in its passage over the chloride of calcium; it is allowed to remain in the apparatus a few seconds, and the exhaustion repeated; these operations are performed in succession ten or twelve times. It is, however, rarely necessary to resort to this process of desiccation, and it is objectionable from the ease with which many compounds rich in hydrogen decompose the oxide of copper at comparatively low temperatures.

The drying tube having been accurately weighed is next fitted to the dried perforated cork, and connected by it air-tight to the retort tube; this is now placed in the furnace, which has been disposed in a convenient place resting on bricks; to the drying tube the potash apparatus, also previously weighed, is attached by a connecting piece of caoutchouc, taking care that the largest bulb is on the arm connected with the drying tube; the potash apparatus should be slightly inclined by placing a cork under the end of the horizontal portion nearest the open extremity. Matters being thus arranged, we proceed to ascertain if the whole be tight, and for this purpose expand the air in the large bulb by heat, so as to expel a few bubbles; if, on cooling, the liquid rise in the limb and maintain its elevation steadily for a few minutes, the combustion may safely be begun. Charcoal broken into pieces about the size of a walnut is ignited in a crucible furnace or by any other convenient means, and when red-hot applied to the portion of the tube nearest the cork where the pure oxide of copper lies; the action of the heat is limited by a double sheet-iron screen which fits into the furnace, and has a central slit which allows it to bestride the tube; this screen can by degrees be moved further and further down the furnace until the whole tube is heated. An additional screen of single iron plate is hung over the closed end of the furnace to protect the cork, which usually should reach to within an inch of the fire, care being taken that the heat never rises so high as to scorch it, or falls so low as to allow of the condensation of moisture in the portion of the retort which projects from the furnace.

When the first part of the retort is red-hot and the escape of air from expansion has ceased, about an inch more of it may be heated, and so the fire gradually carried down; about three bubbles of air may pass in two seconds, it is better not to attempt a more rapid disengagement. At first but a small portion of the gas is absorbed, but when the substance is fairly undergoing decomposition, and the atmospheric air in the apparatus has been expelled, it is almost entirely taken up by the potash-ley. When the whole tube is ignited the heat must be continued till bubbles are no longer disengaged; the potash-ley will now gradually recede into the large bulb; when this is observed to commence, the charcoal must be removed from the tail of the tube; and as soon as the potash has risen to fill half the large bulb, the tip of the tail must be nipped off, and over the opened extremity a tube about eighteen inches long, and one quarter in diameter, should be supported; gentle suction is then effected by a sucking tube (*fig.* 430, D) fitted to the free extremity of the potash apparatus, drawing air through the combustion tube to displace the carbonic acid and aqueous vapour it contains. The use of the long tube over the end of the retort is to supply pure air, and to prevent that from the furnace charged with carbonic acid from passing freely into the apparatus: the actual process of combustion performed in the manner above described usually occupies from an hour to an hour and a half.

The plan of drawing air through the tube is that practised by Liebig, and it admits of considerable accuracy. Dumas, however, connects the extremity of the retort with a drying tube, and this again with a receiver containing oxygen, which gas is carefully driven over the contents of the tube. This renders the operation somewhat more complicated, but it is unquestionably more exact, especially in compounds where the proportion of carbon is great. The tube for supplying oxygen is easily adjusted to the retort by drawing out the tail horizontally instead of obliquely, and fitting it on by a caoutchouc connector, care being taken to screen the junction from the influence of heat.

The apparatus is now dismounted, and the whole allowed to cool; in about an hour the drying tube may be weighed, and the increase of weight carefully noted; one-ninth of the gain indicates the quantity of hydrogen the substance contained; the potash apparatus is also weighed, and three-elevenths of what it has gained shews the quantity of carbon. The deficiency is oxygen.

The oxide of copper used in these experiments may again be rendered serviceable by moistening it with nitric acid, and igniting as before.

2. *Analysis of a liquid not containing nitrogen.*

If the fluid be *volatile*, we take a piece of tube rather less than a quarter of an inch diameter, heat it in the blowpipe flame, and draw on it a capillary portion about four inches long; about a quarter of an inch below this the tube is sealed; the little piece of tube thus left connected with the capillary part is heated and blown into a small bulb about as big as a good-sized pea; this is cut off, leaving a capillary neck of about two inches long. Having made a sufficient number of these little bulbs, we take two of them, which we have ascertained will freely enter the combustion-tube, and weigh them accurately; a little of the liquid to be analysed is put into a small tube, and the capillary neck of the bulbs inverted into the liquid; the bulbs are then warmed by the flame of a spirit-lamp, so that on cooling they shall be about three-fourths filled with the liquid. The necks are now sealed by the blowpipe-flame, and the bulbs again weighed; the increase of weight gives the quantity of the liquid which has entered, and which is to be analysed. The oxide of copper having been heated, and allowed to cool with the usual precautions, about an inch and a half of the retort is filled with pure oxide; we then take one of the bulbs, draw a file across the capillary neck, put the bulb into the tube, break off the neck by pressure against the glass, and drop the broken portion in with the bulb; we then pour in a couple of inches of oxide of copper, introduce the second bulb in the same manner as the first, and fill up the tube with oxide, cork it and strike it smartly on the table as before to secure free air-way. The combustion-tube is now connected with the exhausting syringe, but no heat applied; on gently working the syringe, the air and vapour in the bulbs will expand and drive out the liquid, which will be quickly absorbed by the oxide of copper around; we adjust the apparatus in the furnace as before, and gradually heat the upper half of the tube; when this is red, we volatilize the fluid by cautiously approximating a piece of ignited charcoal, taking especial care not to heat the tube too much; by degrees all the liquid in the first bulb is expelled, and we proceed in like manner with the other; the whole tube is finally heated carefully, and the after part of the process conducted in the manner already described.

If the liquid be *not volatile*, an oily acid for example, a small vessel is made by taking a piece of glass tube about a quarter of an inch in diameter, sealing one end, and while hot pressing it on a flat surface, so as to make a firm basis on which it may stand upright; it should be cut off the tube so that the little vessel be about an inch high. It is weighed at first empty, and a second time with the liquid for analysis; an inch or two of oxide of copper is put into the combustion-tube, then the vessel with the liquid. On inclining the tube sufficiently, the liquid runs out and is made to diffuse itself over the inner surface of the lower half of the tube, which is to be filled with oxide of copper, and the analysis to be cautiously proceeded with in the usual way.

Substances which contain a great excess of carbon sometimes escape complete combustion by this process; when this is feared, all danger may be averted either by adopting the plan of Dumas, already mentioned, or by pulverizing some chlorate of potash finely, which is carefully dried, mixed with about four times its weight of oxide of copper, and the first portion of the retort is filled with it for about an inch; the tail-like prolongation may in this case be dispensed with at the close of the operation; instead of sucking air through the apparatus, we very cautiously apply heat to the chlorate, oxygen is evolved, which burns the last traces of carbon and displaces the gas and aqueous vapour which the tubes contain. When the chlorate has been used, the last inch of oxide of copper must be kept separate from the rest, as it will be mingled with chloride of potassium, and must not be employed again until it has been washed from the salt, for as chloride of copper is slightly volatile it would be deposited in the drying tube and unduly increase its weight. If the heat is too suddenly applied, a portion of the chlorate is apt to be carried forward mechanically, and this constitutes the chief objection to its use.

Sometimes *chromate of lead* is advantageously substituted for oxide of copper with substances difficult of combustion, as by a bright red heat alone it gives off a portion of its oxygen. It is easily prepared by precipitating the chromate or bichromate of potash with solution of acetate of lead. It should be well washed and heated to incipient fusion before it is used for analysis. It has the advantage of being much less hygroscopic than the oxide of copper. To ensure accuracy, when much gas (as in this case, and in instances where nitrogen is present,) passes through the potash apparatus during the whole experiment, it is best to connect the open extremity with an additional drying tube, charged with solid hydrate of potash instead of chloride of calcium, the weight of which has been carefully noted, as a portion, very small but still susceptible, of aqueous vapour is carried off from the solution of potash by the gas, and would otherwise be lost, making the quantity of carbon appear somewhat too little.

3. *Analysis of a body containing nitrogen.*

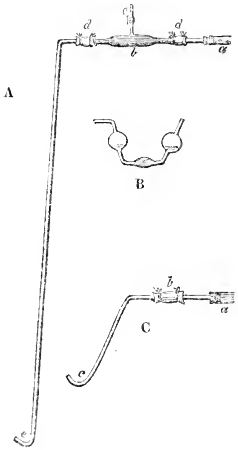
Two separate analyses are in this case required; the first, to discover the proportion of carbon and hydrogen; and the second expressly for the nitrogen. When bodies containing nitrogen are burned with oxide of copper, a variable proportion of the lower oxides of nitrogen is formed, which being retained by the chloride of calcium or potash would render the analyses incorrect. A precaution is therefore employed which renders it necessary to make use of a retort-tube somewhat longer than common; it is charged as usual to within four inches of the opening, and then filled up with clean copper turnings; the apparatus is arranged as before directed, the copper turnings are brought to full redness, and the analysis proceeded with cautiously in the ordinary manner. As the oxides of nitrogen pass slowly over the ignited copper they are decomposed, the oxygen combining with the copper while pure nitrogen escapes; the quantity of carbon and hydrogen is determined exactly as heretofore.

To ascertain the proportion of *nitrogen*, the most accurate method is that recently devised by Varrentrapp and Will, and suggested about the same time by Berzelius; the fundamental fact consists in the observation of Gay Lussac, that when azotised matters are heated with a large excess of hydrate of potash (soda answers equally well), the whole of the nitrogen is expelled in the form of ammonia. In order to render it available for the purposes of analysis the subjoined precautions are requisite.

A mixture of two parts of quicklime and one of hydrate of soda is prepared by slaking some well-burned lime with the necessary quantity of a solution of soda; the whole is evaporated to dryness, ignited, the dry mass pulverized as quickly as possible, and then transferred to well-stopped bottles, in order to exclude carbonic acid and moisture. When an analysis is to be made we proceed as usual, making the mixture in a warm mortar, only substituting the alkalized lime for oxide of copper; the accidental presence of a little moisture, after the weight of material for analysis is accurately known, is of no consequence in this case.

Having introduced the mixture, it is better loosely to plug the aperture of the retort with a few fibres of asbestus (which has been ignited just before) to prevent any mechanical transport of the mixture into the apparatus through which the gases are passed; on applying heat to the combustion-tube in the ordinary way, and with the usual precautions, the substance is decomposed, and the whole of the nitrogen escapes as ammonia. The drying tube and potash apparatus are dispensed with, and the

Fig. 431.



A.—*a*, mouth of the combustion-tube; *b*, three-legged brass tube furnished with the stop-cock (*c*); *d*, *d*, caoutchouc connectors; *e*, glass tube, upwards of 30 inches long, recurved at the lower extremity for delivering gas in the mercurial trough.

B.—Bulb-tube for containing hydrochloric acid in the determination of nitrogen by the method of Varrentrapp and Will.

C.—*a*, mouth of the combustion-tube; *b*, caoutchouc connector; *c*, gas delivering tube.

ammonia is collected by attaching a bulb-tube of the form represented (*fig*. 431, B), air-tight with a good cork, to the retort-tube, the apparatus having been previously charged with hydrochloric acid sp. gr. 1.1, as high as the lines in the figures indicate. Pure hydrochloric acid is easily procured for this purpose by diluting the ordinary acid of the shops till it has a sp. gr. of 1.1, and distilling in glass vessels—the first eighth may be rejected. Distillation may be proceeded with until three-quarters of the acid employed have passed over. It is better for the operator always to rectify his own acid, in order to be quite sure of the absence of any trace of ammonia. The tube connecting the bulbs should be somewhat larger in diameter than that of the ordinary potash apparatus, in order to allow the liquid to be poured out readily. When the operation is complete, absorption will take place and the fluid rise in the bulb nearest the fire; at this moment we nip off the top of the combustion-tube and draw air carefully through the apparatus in the usual way. When the combustion is terminated, the contents of the bulb-tube are emptied into a small evaporating dish, and the apparatus washed out first with a little alcohol and ether, and afterwards several times with water; some solution of bichloride of platinum is added, and the whole evaporated to dryness by a water-bath or chloride of calcium bath; when dry, it is digested with a mixture of two parts of alcohol, sp. gr. 833, and one of ether, which dissolves the excess of bichloride of platinum, and leaves the double chloride of platinum and ammonium in a crystalline form.

This must now be brought upon a weighed filter, (or better, upon two filters, one of which has been counterpoised against the other,) and washed repeatedly with the mixture of two parts of alcohol and one of ether until nothing further is taken up; the precipitate and filters must be dried by a water heat and the weight accurately observed. According to Varrentrapp and Will, 220.52 grs. of the ammonia-chloride are equivalent to 14 grs. of nitrogen; the estimate of these writers is too high, and 225 grs. are more nearly equal to one equivalent or 14 grs. of nitrogen. Practically, however, their calculation is very near the truth, as during the operation a minute quantity of hydrochlorate of ammonia escapes uncondensed, and the two errors compensate each other.

This method of determining nitrogen answers for all cases excepting those in which it occurs in the form of nitric acid, when it must be determined by volume and its weight thence deduced. For this purpose the process of Dumas is the most trustworthy. A retort tube of about twenty inches long is employed; not drawn out into a tail, but sealed with a rounded extremity; about two inches of the tube are filled with carbonate of copper or of lead, and then the mixture with oxide of copper added and covered as usual with a layer of pure oxide; beyond this the last two or three inches of the tube are filled with clean copper turnings, as already directed, to decompose any of the oxides of nitrogen which may be formed. The retort tube is then connected with a three-legged apparatus of brass or copper (*fig*. 431, A, *b*), one limb of which is furnished with a stopcock (*c*). The connection with the retort is best made by passing a piece of glass tube through a cork fitting accurately into the mouth of the combustion tube and connecting the brass apparatus to this small glass tube by a caoutchouc connector; the limb (*b*) is fastened by a similar joint to a glass tube (*e*) bent at right angles near one end, with a straight portion upwards of thirty inches long, the other extremity of which is turned up at an acute angle for the convenience of safely delivering the gas; the tube is placed in a vertical direction with its lower upturned extremity dipping into a small mercurial trough; the stop-cock tube (*c*) is connected with an exhausting syringe and a vacuum produced; the apparatus is left for half an hour to ascertain that all the joints are tight: if the mercury after this lapse of time still stands at the same level, the experiment is proceeded with; a moderate heat is applied by a spirit lamp to the end of the retort containing the carbonate; by this means carbonic acid is set free and displaces the last portions of air; the exhaustion and disengagement of gas are repeated alternately three or four times, taking care to leave sufficient carbonate undecomposed to renew this expulsive process at the termination of the experiment. The stop-cock (*c*) is now closed, the air-pump is removed, and a graduated jar containing some solution of potash is inverted in the mercury over the recurved extremity of the long glass tube. The copper turnings are then brought to redness in the usual way by charcoal, and the experiment conducted with the customary precautions, the decomposition being caused to take place less rapidly than usual; when the part of the retort containing the matter for analysis is red-hot through its entire extent, heat is gradually applied to the carbonate at the end, and the last portions of gas from the combustion in the apparatus are driven into the receiver by the disengaged carbonic acid.

As the products of combustion are only water, carbonic acid, and nitrogen, the two former are retained by the solution of potash, whilst the latter alone presents itself for measurement. I need hardly say that the height of the barometer and thermometer must be carefully noticed, when the apparatus by standing for an hour or two has reached the temperature of the atmosphere; as the gas will be saturated with moisture, its volume must be corrected by the known methods for the three points of temperature, pressure, and moisture; then, since 100 cubic inches of nitrogen at standard temperature and pressure weigh 30.15 grs., the weight of the nitrogen that a given quantity of the matter analysed contains is easily determined. In this process, as in every case where the proportion of nitrogen alone forms the object of our experiment, after the weight of the material for analysis has been once accurately determined, it is evident there is nothing to fear from the absorption of moisture.

Occasionally the quantity of nitrogen, where large, is advantageously determined by making the combustion just as though we were going to ascertain the proportion of carbon and hydrogen; but, instead of condensing the carbonic acid and weighing it, the whole of the gases produced are collected over mercury. A bent gas-delivering tube is substituted for the usual drying apparatus. (*Fig.* 431.) In this case it is best to begin at the closed extremity of the tube, and having expelled the atmospheric air by a portion of gas generated from the substance, to collect the rest of the gaseous products in a graduated jar; by agitating the gas with solution of potash the proportion of nitrogen to carbon is at once determined, as equal volumes of carbonic acid and nitrogen represent single equivalents of carbon and nitrogen. It is not necessary in this case to determine accurately the quantity of material acted upon.

Experience has shewn that in the preceding process for organic analysis the quantity of hydrogen deduced from it is always slightly in excess, usually about 0.2 parts in 100, whilst, unless chromate of lead or chlorate of potash is employed, the carbon is sometimes as much deficient. A deficiency of carbon also occurs if the ash contain carbonates in any form. Occasionally sulphur and chlorine are among the constituents of organic bodies; the methods of analysis must then be modified. For details upon these subjects the reader is referred to the treatise of Berzelius.

We will suppose the labour of analysis thus brought to a successful issue. It is, however, evident that the information derived from this source alone is but scanty, as we can thereby form no idea either of the number of equivalents of each element entering into the composition of an organic body, or of its relations to the substances concerned in its production or obtainable from it by its decomposition. Whenever it is possible, the equivalent or combining proportion of the compound must be determined. This is effected by preparing a compound of the body with some substance, whose equivalent is well known, and proceeding to analyse the new product. If our organic substance be soluble in water, and capable of entering into combination with oxide of silver, this oxide is for many reasons preferred. Oxide of silver combines with very many organic bodies, and forms with them compounds insoluble or sparingly soluble in water. They may generally be formed by double decomposition, and washed from all adhering impurities; fifteen or twenty grains of the silver compound is accurately weighed in a counterpoised porcelain crucible. It is then carefully incinerated till pure silver alone remains. On again weighing, the loss will give that of the body combined with the silver, and in addition that of one equivalent of oxygen expelled from the oxide of that metal at a red heat. The residual silver should dissolve without remainder in nitric acid. Now, since the equivalent number of silver on the hydrogen scale is 108, it is evident that by simple calculation we may determine the equivalent number of the organic body that had combined with it.

An example will perhaps elucidate my meaning more distinctly.

48.73 grs. of acetate of silver left
31.49 grs. of metallic silver.

———

17.24 grs. will therefore express the loss, due to the united weight of acetic acid and oxygen combined with the silver.

31.49 : { Equ. of sil. 108 } : : 17.24 : x (=59)

59— { 1 equ. oxy. 8 } = 51, the equivalent number of acetic acid.

Another example will shew the method of calculating the number of equivalents of each element in the compound.

By analysis with oxide of copper we find 10 grs. of acetate of silver yield
5.277 grs. of carbonic acid and
1.620 grs. of water

and calculating from the previous experiment..	6.462 silver,
this is equivalent to	1.439 carbon
	0 180 hydrogen
The deficiency is	1 919 oxygen.
	10.000

Then by proportion—

Silv.		Eq.sil.			C.
6.462	:	108	: :	Carb. 1.439 : x (= 24), or	4
					H.
6.462	:	108	: :	Hydrog. 0.180 : x (= 3), or	3
					O.
6.462	:	108	: :	Oxygen 1.919 : x (= 32), or	4

Total.. = 59
deduct 1 equivalent of oxygen 8

and we obtain the equivalent of anhydrous acetic acid.. } 51, or { C 4, H 3, O 3 }

Sometimes no compound with silver can be obtained, and a salt of lead is then, if practicable, substituted for it. The residue, however, in this case does not consist entirely of metallic lead, neither is it all oxide of lead. It is carefully weighed, treated with acetic acid in the crucible itself; the oxide of lead is thus dissolved and washed away. When the contents of the crucible have been carefully dried, a second weighing gives the quantity of metallic lead, whilst the loss furnishes that of the oxide. From the metal we calculate the quantity of oxide to which it is equivalent; this added to the portion dissolved by acetic acid furnishes the whole quantity of oxide contained in the compound:—a calculation similar to that employed for the silver salt, then supplies us with the means of determining the equivalent number of the body analysed. This method is not quite so accurate as the preceding; it involves more manipulation, and the compounds of lead are apt to undergo slight loss by volatilization at a high temperature.

It would here be out of place to enter into detail into the methods of checking the correctness of an analysis in its various parts. Upon this point the reader is referred for information to Liebig's Introduction to Organic Analysis. The subject is an important one, and by no means sufficiently attended to by the majority of those who devote themselves to analytical researches of this description.

The number of authors who have written upon the methods of analysis is very great; and their instructions are found more in detached papers, scattered through the various scientific periodicals than in systematic treatises.

The works which may be consulted with especial advantage on proximate analysis are Berzelius's Lehrbuch Der Chemie, third German edition, translated by Wöhler, 10 vols. 8vo.; the fourth edition of Prout's Treatise on Diseases of the Stomach and Urinary Organs, and his papers in the Medico-Chirurgical and Philosophical Transactions; G. O. Rees on the Analysis of Blood and Urine; Lecanu, Ann. de Chimie, xlviii., and various papers on the blood; Simon, Handbuch der augewandten Medizinischen Chemie, 2 vols. 8vo. 1840-42; one of the most recent and best treatises on animal chemistry, full of laborious and careful analyses, with copious and accurate directions for their performance. This work is now being translated into English.

For directions for analysing the inorganic constituents of organized compounds the reader is referred in particular to Rose's Analytical Chemistry, either the fourth German edition, or the English translation of the first edition by Griffin.

Ample instructions for the ultimate analysis of organic substances are furnished in Liebig's Organic Analysis, translated by Gregory, and forming one of the series of works published in Griffin's Scientific Miscellany, and in the fifth volume of Dumas' Traité de Chemie Appliquée aux Arts, as well as in the volumes of Berzelius already referred to.

A valuable treatise has recently been published in German by Vogel, jun. on the application of the microscope to the field of animal organic chemistry—"Anleitung zum Gebrauche des Mikroskops zur Zoochemischen Analyse und zur Mikroscopisch-chemischen untersuchung uberhaupt."

(W. A. Miller.)

OSSEOUS SYSTEM. (COMPARATIVE ANATOMY.)—One of the most striking and distinctive characters peculiar to the highest grades of animal existences, the VERTEBRATA, is that they have their bodies supported by, and as it were moulded upon, an internal frame-work, which is generally made up of numerous pieces, very various in their forms and uses, which are called the *bones;* and the assemblage of them, whatever their modification, constitutes the *skeleton.*

Seeing the great diversity of forms and habits in the innumerable races of animals constituting this great group of living beings, some being specially appointed to occupy the waters of our globe, others to inhabit the marsh and the swamp, whilst others again tread the firm surface of the ground, or raise themselves into the regions of the thin air; and that under all the diversified shapes of Fishes, Reptiles, Birds, and Mammifers, we are prepared, *à priori,* to expect, in the construction of this skeleton, varieties correspondingly great both in the materials employed and their mechanical arrangement, inasmuch as the machinery employed for effecting progression under circumstances so dissimilar must be changed in every race, and adapted to the peculiarities of habit conferred upon any given creature.

The substance of which the internal skeleton of a vertebrate animal is composed differs moreover very remarkably from that employed to build up the organs of support in any of the other divisions of the animal kingdom. In all the great group of Radiata (Cuv.), wherever a hard material is employed, it is built up by the slow external accretion of earthy particles deposited in successive layers from the living substance of the body, arranged not unfrequently with admirable precision; but, when once formed, such a skeleton is entirely devoid of vascularity, and almost placed beyond the reach of vital influences. Throughout all the Articulata the skeleton is an external crust exuded from the surface of the skin, which is so entirely destitute of all capability of growth or expansion, that it must be cast off frequently during the life of the animal, to be renewed again and again as the bulk of its body is enlarged. In all the Mollusca, too, with the exception of the Cephalopods, in which a true bony structure begins for the first time to be developed, all the hard parts of the body are cuticular and composed of shell. In the Vertebrata alone is found a real osseous skeleton nourished by bloodvessels, consisting essentially of a living tissue that is capable of constant growth and renovation, having its texture hardened in proportion to the necessities of the case by an interstitial deposit of various earths, especially of phosphate of lime, which is continually removed and renovated as age advances, and, in short, is subject, during the whole existence of the creature, to vital influences, its hardness and composition being subject to great variations. In making use of the terms *bone* and *osseous tissue*, we must therefore be understood by no means to employ these words as indicating portions of the animal fabric endowed with any particular degree of density or firmness, that being entirely an adventitious circumstance depending upon the greater or less abundance of the earthy matters deposited in the living tissues, and even in the same animal, in this respect, offering at different periods of its life the most opposite conditions.

In the lowest and most feeble Fishes, which, in consequence of their sluggish movements through an element that buoys them up on all sides, no firmness is required in any part of their construction, and few of the locomotive levers met with in more highly-gifted forms are present, the whole osseous system consists permanently of the softest cartilage undivided as yet into distinct pieces; and it is only as we ascend from this point through successive groups of Cartilaginous Fishes as they are called, the *Sharks, Rays, Sturgeons,* &c., that, owing to an increased deposit of the hardening earths within the cartilaginous web, firmness and solidity are slowly given. Even in the most perfect Fishes the bones remain soft in comparison with their condition in terrestrial Vertebrata, whilst it is only in Carnivorous Mammalia, and more especially in Birds, that the maximum of hardness is conferred upon the osseous system, a density and a strength commensurate with the powerful muscular exertions required by the conditions under which those races live. Equally remarkable are the differences observable in the texture of the osseous skeleton at different ages in the same creature The Tadpole of the Batrachian Reptile, for example, at the time when it commences its earliest struggles in the element wherein it passes the first portion of its existence, is, as relates to the condition of this part of its economy, inferior even to the *Myxine* and the *Lamprey* amongst Fishes, consisting of the most delicate cellulosity or of the softest gristle. As growth proceeds, osseous particles accumulate, and the condition approximates that of the more perfect Fishes. Lastly, as the anterior and posterior extremities sprout, the bones acquire progressively the density essential to the construction of a terrestrial animal, and the whole internal framework becomes consolidated to an extent proportioned to the vigorous movements of the perfect Frog. In the higher Mammalia the succession of the phases of developement is still further prolonged. At its first appearance, the osseous system is represented by a mere web of cellular tissue, which slowly attains to a cartilaginous texture; this cartilage, during fœtal growth, is converted into bone by the deposition of earth in its substance; but it is not till long after birth, when adult age has need to exert all the energies of life, that the bones are fully formed, hardened, and lightened to the utmost required extent by consolidating their substance to the *maximum*, and excavating the caverns and cancelli that characterize the most perfectly matured conditions of the osseous framework.

But passing from these general views, for a more complete consideration of which the reader is referred to another article, (OSSEOUS TISSUE,) we proceed to examine more closely the composition and developement of the skeleton, and here we find difficulties to be encountered of no common kind. Did the skeleton invariably consist of the same number of bones, only modified in their shape or position according to the necessities of the different races of Vertebrata, the task of the comparative anatomist would be easy when he came to investigate their analogies and relations with each other; but this is far from being the case: the skeleton of the adult animal does not present the same number of pieces as that of the same creature in a less advanced condition, numerous parts, originally distinct, having become fused and consolidated into one; and, on the other hand, the juvenile being differs from the embryo from circumstances precisely the reverse, seeing that the full complement of bones or centres of ossification has not as yet been developed. Now, as in ascending the scale of living beings belonging to the Vertebrate division of the animal creation, we find that nature can arrest the further advance of ossification at any assignable point of developement, leaving some parts permanently atrophied, while others are allowed to attain their full growth, we find great varieties in the composition of the osseous framework. The *Tadpole*, were its growth arrested before its limbs begin to sprout, would be a *Fish*. The *Frog*, if it ceased to grow when its limbs were but partially formed, would be a *Siren* or a *Proteus*, having little or nothing in common with the adult creature as regards the configuration or even the number of the bones in its skeleton. Which of the three conditions must the comparative anatomist refer to in order to estimate the condition of the bones composing the framework of this Batrachian? The importance of this inquiry will be at once obvious, as, either in the first instance there must have been a much greater number of bones developed than are met with in what is usually considered a complete skeleton, or in the adult animal the bones have become too much confused with each other to allow us at all to estimate their real condition. It is sufficient indeed for any person who is only acquainted with the osteology of man, to cast his eyes over the bones entering into the composition of the skeleton of a fish to perceive at once that the nomenclature employed by the human anatomist is by no means sufficiently ample to afford names to one-half of them, which indeed have no representatives in the human body; or even the bare comparison of the adult human cranium with that of the infant of tender age would convince us that in the former there are many more distinct bones than in the latter. The only mode of solving these difficulties is obviously to study the composition of every part of the skeleton in the most complicated form under which it is met with, and having ascercertained the number and disposition of the pieces of which it then consists, and settled the names and analogies of each, it becomes comparatively easy to point out what parts are deficient in less complex forms of the skeleton.

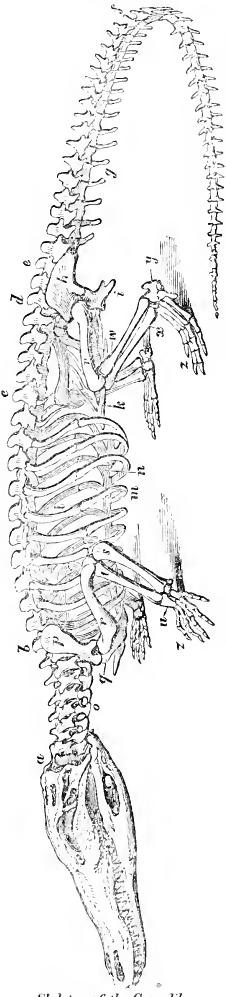
The number of pieces which can normally enter into the construction of any portion of the osseous apparatus having been thus determined, these are regarded as the primary *elements* of the skeleton, by the developement, suppression, enlargement, or modified form of which every required variety of the bony framework may be explained, and the construction of this portion of the animal economy proved to be in accordance with certain immutable laws that may be traced throughout the immense series both of the existing and of extinct races of Vertebrata.

It will readily be perceived after the above remarks that a perfect skeleton, that is, a skeleton presenting all the parts of which it might normally be composed in a complete state of developement, does not exist in nature.

A spinal column may exist alone without either cranium, face, or limbs, as is the case in that strange and rare fish the Amphioxus.* Or the spine, cranium, face, and extremities may coexist without ribs or thorax, as in the *Frog*. The spine and cranium form almost the entire skeleton of many apodal Fishes, while in Serpents the ribs become the chief instruments employed in locomotion, not even vestiges of legs or arms being visible.

Imagining, however, that a fully formed skeleton, having every apparatus belonging to it, could be pointed out, let us now proceed briefly to glance at the parts of which it would consist, and these we should find to be the following.

Fig. 432.



Skeleton of the Crocodile.

* Vide a Memoir on the structure of this extraordinary production of nature, by John Goodsir, Esq.

1. The *spinal column*, the centre of the whole fabric enclosing in a canal formed by arches surmounting its dorsal aspect the medulla spinalis or the axis of the spinal portion of the nervous system.

2. The *cranium*, essentially composed of vertebræ; but here, in consequence of the enlarged size of that part of the cerebro-spinal axis of the nervous apparatus placed within them, exaggerated in size and modified in form.

3. Of a frame of bones appended to the anterior part of the cranium for the lodgement of the organs of those senses that are immediately in connection with the encephalon, forming what, taken collectively, is called the *face*.

4. Of a *hyo-branchial* apparatus forming the framework of the throat, and supporting the organs connected with aquatic respiration. These last of course are only present in animals breathing by gills, and can only be expected to exist in a state of complete developement in the class of Fishes.

5. Of the *thoracic apparatus*, composed of two sets of ribs—a dorsal and a sternal series—and of the sternum, which itself, when fully developed, is made up of numerous bones.

6. Of a pair of *anterior extremities*, divisible into shoulder, arm, forearm, carpus, metacarpus, and digits.

7. Of a pair of *posterior extremities*, constructed after the same model as the last, and presenting corresponding parts, to which the names pelvis, thigh, leg, tarsus, metatarsus, and toes are respectively appropriated.

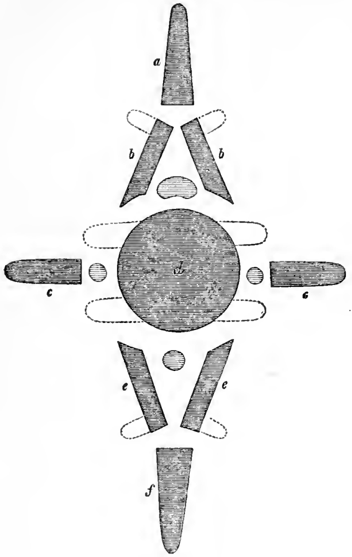
The most complete skeleton with which we are acquainted among existing Vertebrata is that of the *Crocodiles*, the study of which cannot be too strongly recommended to the comparative osteologist, as in these creatures all its parts remain permanently in a medium condition, so that the arbitrary divisions of the skeleton adopted by the human anatomist are at once recognisable, although we find others which in Man have no existence. The spine is divisible into a cervical region (*fig*. 432, *a*, *b*) interposed between the cranium and the thorax, although ribs (*o*) are appended even to the cervical vertebræ. The dorsal region (*b*, *c*) supporting the thoracic ribs, the lumbar (*c*, *d*), the sacrum (*e*), and the caudal (*f*) are distinguishable for the same reasons as in the human subject, notwithstanding that the caudal portion resembles anything rather than the human *os coccygis;* for here, so far from its being formed merely of the rudiments of the bodies of almost obliterated vertebræ, the processes form very powerful levers, and of these there are some developed inferiorly (*g*) of which no vestiges exist in the human skeleton. The bones of the cranium and face are far more numerous than in the skull of our own species, as we shall explain more minutely hereafter: see *fig*. 441, where they are delineated on an enlarged scale. The thorax consists of dorsal ribs (*l*) and of sternal ribs (*m*), which are equally important elements of the skeleton and of the sternum, here situated much as in the human subject. Behind the sternum, moreover, and extending from it quite to the pubic bones, there is in the Crocodile a set of ventral ribs (*k*) to which in Man there is nothing analogous, except, perhaps, the tendinous intersections still lingering in the recti muscles of the abdomen. The shoulder (*p*, *q*) consists, like the pelvis (*h*, *i*), of three distinct and important bones, while all the pieces entering into the formation of the extremities very nearly resemble what is met with in the human subject.

Having premised thus much, we may now, without further preface, plunge more deeply into our subject, and, taking in detail all the elements that are recognised by modern anatomists as belonging to the osseous system, examine them separately in the various aspects under which they present themselves in the different classes composing the Vertebrate portion of animated nature.

Spinal column.—Commencing our analysis of the skeleton by an examination of the spine as being the most essential portion of the osseous system, the primary or central part to which all others that are met with in the different classes of Vertebrata may or may not be superadded in accordance with the conditions under which they are appointed to exist, we shall soon perceive that both in texture and composition it offers very important varieties. In the Myxine and Lampreys it is a simple stem of extremely soft cartilage, almost gelatinous in its consistence, which traverses the axis of the body, presenting, when superficially examined, no appearance of division into separate vertebræ; and it is not uninteresting to observe how, advancing from this simplest form of spine through various tribes of Fishes, its separation into distinct pieces is gradually effected. But even in the Lamprey, on strict examination, there are perceptible in the arches that embrace the spinal canal and on the surface of the soft cord that represents the bodies of the vertebræ, slight indications of an incipent division into vertebral pieces, which are represented by slender rings of ossific matter that encircle at intervals the soft cartilage upon which they sensibly encroach. In a more advanced form of the spine, these ossified rings are considerably increased in their relative proportions, and encroach further and further upon the cartilaginous stem until they penetrate even to its centre, and are then no longer dubiously the representatives of the bodies of so many vertebræ. In the generality of Fishes, indeed, the central part remains unossified, so that a cartilaginous axis traverses the vertebral column from end to end. At last even this is obliterated, and the vertebral centres are completely formed.

But even before the bodies of the vertebræ are thus perfected, the laminæ destined to enclose and protect the spinal cord are fully formed by the deposition of osseous matter, as may be readily seen in the Sharks and Rays and many other cartilaginous Fishes, in which, although the complete consolidation of the body has not yet been achieved, the spinous and other processes destined to form the fulcra upon which muscular action is to be exerted are so ossified as to afford the needful solidity and strength. In these races of Fishes, indeed, the condition of the spinal column is not a little remarkable, inasmuch as in the *Skates* the anterior vertebræ are so consolidated by an

Fig. 433.



Elements of a vertebra (after Owen).

encrustment of bone as to resemble a single mass; and in both the Rays and Sharks there are many more laminæ enclosing the spinal canal than there are bodies of vertebræ, bony plates being developed over the junctions of vertebral centres with each other as well as in the usual situation,—a circumstance which might at first sight seem to militate against the views adopted by modern physiologists concerning the elemental constitution of this part of the body, but from which, in reality, no legitimate inference is deducible, seeing the extremely confused and incomplete progress of ossification in all the cartilaginous Fishes.

Advancing to the osseous Fishes, such confusion no longer exists, and every vertebra assumes a precise form corresponding with the particular uses assigned to it in the region which it occupies. Before, however, proceeding further, it behoves us to resolve an isolated vertebra into the primary elements of which it may itself be made up, and then we shall understand how all the varieties of shape presented by these bones are easily obtainable by the simple exaggeration, diminution, or suppression of some of the elements composing it.

Geoffroy St. Hilaire was the first anatomist who pointed out the importance of thus analysing the different portions of the osseous system, and the views which were promulgated by that learned writer were generally adopted until Professor Owen, in the course of his researches concerning the composition of the skeletons of extinct British Reptiles, was led, as we think very justly, to modify considerably the views which had been previously entertained upon this subject; we cannot therefore do better than lay before the reader the conclusions deduced by Professor Owen from a very elaborate and extensive survey of the various forms of the skeleton.

"A vertebra," says Professor Owen, "may be traced through its various degrees of complication, either during the progressive stages of its developement, or by taking permanently-formed vertebræ of different grades of complexity in different animals; or in many instances by comparing the vertebræ in different parts of the spine in the same animal."

The terminal vertebræ of the tail in most species exhibit the simplest condition of these bones. The most complicated vertebræ are those of the lower part of the neck of certain birds, as the Pelican, or at the beginning of the tail of a Python or other large Serpent.

The parts or processes of such a vertebra may be divided into *autogenous*, or those which are independently developed in separate cartilages, and *exogenous*, or those which shoot out as continuations from these independent constituents. The autogenous or true elements are—

1. The *centrum* or body of the vertebra (*fig*. 433, *d*,) which in Mammalia, as Cuvier has observed, is complicated by two *epiphyses*.

2. Two superior laminæ (*b*, *b*) developed to protect the great nervous cord which rests on the upper surface of the centrum, and which Professor Owen therefore proposes to call *Neurapophyses*.

3. Two inferior laminæ (*e*, *e*) developed generally to protect the great bloodvessels on the under surface of the centrum, and which may be called *Hæmapophyses*.

4. The superior spinous process (*a*) which is connected and generally anchylosed with the distal extremities of the *neurapophyses*, and forms, in conjunction with those processes, the superior arch of the vertebra.

5th. An inferior spinous process which is connected and commonly anchylosed with the distal extremities of the *Hæmapophyses*, forming in conjunction with these a chevron or V-shaped bone.

To the category of autogenous vertebral pieces likewise belong the ribs (*c c*), which are generally anchylosed to the other vertebral elements in the cervical, sacral, and caudal vertebræ of the warm-blooded Vertebrate classes.

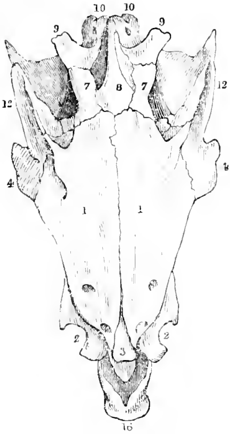
The propriety of regarding the ribs as vertebral elements is well illustrated in the *Plesiosaurus*, in the cervical, sacral, and caudal vertebræ of which they have been generally described as transverse processes, although they are separate bones.

True transverse processes are always *exogenous*, or mere projections from the centrum or the *neurapophyses*, and are of secondary importance. They are of two kinds, superior and inferior; both are present in the cervical vertebræ in most classes of the vertebrated animals; the inferior transverse processes alone are developed in Fishes.

The oblique or articulating processes are also exogenous, and may be developed either from the neurapophyses or the base of the superior spines of the vertebræ.

As in other complicated bones resulting from

Fig. 434.



Skull of the Perch (Perca fluviatilis), after Cuvier.

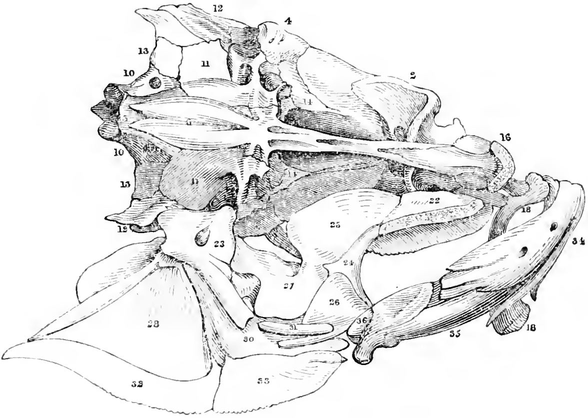
an association of several osseous pieces, certain elements of a vertebra may be modified in position and proportions so as to perform the ordinary functions of others which may be atrophied or absent: thus in Fishes the inferior transverse processes are gradually bent downwards until in the dorsal region their extremities meet and perform the functions of the hæmapophyses.

From the vertebral elements named above every possible variety is presented by these bones throughout all the races of animals possessing them. The body alone (*fig.* 433, *d*) may be developed without the addition of any of the other parts, as in the terminal bones of a Mammal's tail or of the human *os coccygis*, or the neurapophyses may exist without an ossified body, as in some cartilaginous Fishes. The vertebræ of the human skeleton present body, neurapophyses, neural spine, and transverse processes, as do the rib-bearing vertebræ of the Fish. The caudal vertebræ of the Fish, in order to give the great vertical expansion required in this region of their skeleton, have the centre, the neurapophyses, and neural spine as well as the hæmapophyses and hæmal spine to the exclusion of the transverse, while in the earlier caudal vertebræ of the tail of the Crocodile (*fig.* 433, *g*) all the elements enumerated exist in a medium state of developement.

From these data, therefore, the osteologist is enabled to explain the composition of any vertebra that may be offered to his inspection; nevertheless there are numerous apparent exceptions which are well calculated to puzzle the student, met with, especially in the vertebræ of *Serpents* or of the neck of some *Birds*, where the processes are so complicated by the bifurcation of their extremities, or by foramina passing through their roots, or the great size of the articulating processes, or lastly, by the exuberant deposition of osseous matter in particular parts of the bone, that the greatest possible distortion may easily be produced without at all violating the prescribed laws in accordance with which the osseous system is organized. Not unfrequently indeed stunted ribs, or even derivations from the exoskeleton, may become consolidated with the proper vertebral elements in such a manner as not to be readily distinguishable from them, producing additional complications which are sometimes very embarrassing.

Skull.—The osseous framework of the head appended to the anterior termination of the spinal column is by far the most complex part of the skeleton, being composed of very numerous bones connected together by suture or otherwise, but differing marvellously in their

Fig. 435.



Base of skull and opercular bones of Perch.

character and entering into the formation of very numerous and diversified sets of organs, which have in reality no alliance with each other except that of mere juxta-position.

One compartment in Man, exceeding in size all the rest put together, but in the lower Vertebrata forming but a very small part of the whole, is obviously merely a continuation of the vertebral canal lodging the most anterior ganglia of the cerebro-spinal axis, which it arches over and defends, at the same time affording passage to the nerves that emanate therefrom, being essentially itself composed of vertebræ, although, in consequence of the preponderating size of the brain over the spinal ganglia behind, considerable distortion is required, a distortion which in human beings is necessarily carried to such an extent that the normal construction of this part of the skeleton is in man almost wholly indistinguishable. As the vertebral column forms the centre and support of the trunk and limbs, so does the cranial portion of the skull sustain various additional apparatus, which may be enumerated as follows.

1. The auditory apparatus most frequently enclosed in a special bone, the *petrous*, and intercalated among the proper bones of the cranium.

2. The *temporal* apparatus, which in man is confused into a single irregular mass that forms part of what the human osteologist calls the *temporal bone*, but which in the lower Vertebrata, such as the Reptilia, consists of several important pieces, which being withdrawn from the composition of the cranial box are employed for the articulation of the lower jaw, and moreover in the osseous Fishes sustain the bones of the gill-covers. (*Nos.* 12, 13, 23, 26, 27.*)

3. The *pterygo-palatine* apparatus represented in the human skeleton by the internal *pterygoid processes* of the (so-called) sphenoid and the *ossa palati*. These form the framework of the fauces. (*Nos.* 25, 22.)

4. The *olfactory apparatus*, into the composition of which enter the *æthmoid*, over which the nerve of smell is more particularly distributed, together with the *nasal*, the *superior maxillary*, the *vomer*, the *inferior turbinated bones*, and others more remotely connected with the formation of the cavity of the nose. (*Nos.* 3, 20, 16, 18, *d.*)

5. The *orbito-lachrymal apparatus*, or the bones which assist in forming the orbital cavity and lachrymal passages.

6. The *superior maxilla* formed of the *maxillary* and *intermaxillary bones*. (*Nos.* 18, 17.)

7. The *inferior maxilla*, which in the lower animals consists of several pieces, to be more fully noticed hereafter.

Before proceeding to describe the individual bones that enter into the composition of the cranial portion of the skull, in order to lay before the reader the comparative structure of that important portion of the skeleton, it will be

* The following table, showing the numbers by which the corresponding bones appertaining to the cephalic portion of the skeleton are indicated in all the figures, is given to facilitate comparison between them.

1	Frontal.	18	Maxillary.
2	Anterior frontal.	20	Prænasal.
3	Nasal (*æthmoid, Cuv.*)	22	Palatine.
4	Posterior frontal.	23	Masto-temporal.
5	Inferior occipital.	24	Transverse.
6	Sphenoid.	25	Internal pterygoid.
7	Parietal.	26	Zygomatic.
8	Supra-occipital.	27	Squamo-temporal.
9	External occipital.	28	Opercular.
10	Lateral occipital.	29	Styloid.
11	Alar.	30	Præopercular.
12	Mastoid.	31	Symplectic.
13	Petro-temporal.	32	Subopercular.
14	Ingrassial.	33	Interopercular.
15	Œthmoid (*anterior sphenoid, Cuv.*)	34	Dental.
16	Vomer.	35	Supra-angular.
17	Intermaxillary.	36	Angular.
		g	Suborbital plates.

Fig. 437.

Hyoid apparatus and branchiostegous rays of Perch (after Cuvier).

proper to examine how far it is entitled to be looked upon as we have already stated it to be, as forming a continuation of the spinal column, and if so, to define the vertebræ of which it consists. In the human cranium indeed this would be no easy task, partly in consequence of the extreme exaggeration of every element composing it, and partly from the manner in which some bones, distinct in the lower animals, are here consolidated into single masses; moreover in consequence of the prodigious developement of the cerebral hemispheres every part is distorted and pushed aside as it were out of its proper situation relative to the neighbouring bones.

In the cranium of the Reptile, however, and even of the less intelligent Mammalia, these difficulties are to a great extent done away with, and the vertebral form is preserved, while, in addition, the elements composing them frequently remain permanently disunited.

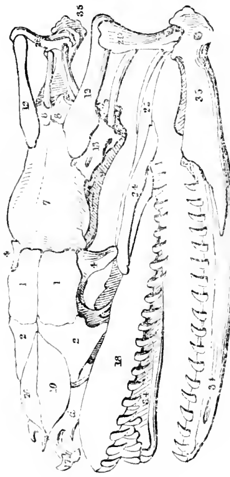
The first cranial vertebra (commencing from behind) is the *occipital*, and this can present no difficulty. In Fishes, indeed, and in many Reptiles, the *occipital bone*, of which this vertebra is entirely made up, has not only the exact shape of one of the spinal bones, but the elements composing it remaining often permanently disunited, they are most easily and satisfactorily identified. Inferiorly there is the body (or basilar bone, 5) connected with the body of the first spinal vertebra in the same manner as the corresponding portion of the other vertebræ are connected with each other. On each side the neurapophyses (or *extra-occipital bones*, 10) arching over the commencement of the spinal cord, and lastly, the neurospine (or *supra-occipital bone*, 8) occupying its normal situation, and in many of the lower Vertebrata forming a real spinous process, although in the human subject, owing to the prodigious size of the hinder part of the encephalon, it is enormously spread out in proportion to the dimensions of the parts it protects.

The second or *parietal vertebra* of the cranium is slightly more distorted, and its real nature masked, particularly in the higher Vertebrata, by the interposition of the petro-temporal bone, which does not normally belong to the cranium, between it and the preceding. Its body is the *sphenoid bone*, represented in the human subject by the posterior part of the *sella Turcica*, but which in Reptiles is a distinct element of the skull; its arches are formed by the *alæ majores* of the *sphenoid*, (likewise separate pieces of the cranium in the lower animals, although in man they are consolidated with the former,) while the spine is converted into the expanded parietal bone or bones spread out over the central regions of the brain.

The anterior cranial vertebra is called the *frontal*, receding still more from the normal appearance of a vertebra than the parietal, the preponderance of magnitude in the different elements that form it being completely inverted, the body being quite rudimentary, while the enormously developed spinous elements are now converted into frontal bones. In man its body and its arches are represented by the *alæ minores* of the sphenoid or *ingrassial* bones, and the *os frontis* constitutes its disproportionately expanded spine. These three vertebræ, therefore, are the essential constituents of the skull; and, although in the human cranium the most aberrant of any met with in creation, their nature is not at once obvious; it is only necessary for the student to recur to less distorted forms of the head at once to recognise the reality of the resemblance.

Should other proof indeed be wanting, the manner in which all the cerebral nerves make their exit from the cranium would in itself offer a convincing argument. In every other part of the cerebro-spinal axis the nerves invariably are given off through passages situated between contiguous vertebræ, which are called, from this circumstance, *par excellence*, *intervertebral foramina;* nay, so sure is this guide, that in those instances where the vertebral pieces are confused, so as to be otherwise undistinguishable from each other, the position and number of these foramina is sufficient to indicate the number of vertebræ of which the part of the skeleton in question originally consisted, before the pieces composing it became permanently anchylosed. Precisely in the same manner the nerves derived from the encephalon pass out through the interspaces between the occipital and parietal vertebræ, or between the latter and the frontal; and, although from the great bulk of the encephalic masses and the number of nerves derived therefrom, the passages through which they principally escape have been named *foramina lucera*, indicating their size and irregularity;

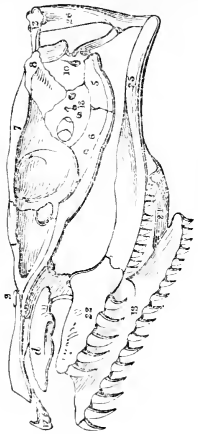
Fig. 438.



Skull of Boa Constrictor.

they are not on that account less the representatives of the intervertebral foramina properly so called. The mere circumstance of the channels of some of these nerves being, in the human subject and in other Mammifera, circumscribed by rings of bone and thus converted into distinct foramina, to which special names have been given by the human osteo-

Fig. 439.



Section of skull of Boa.

logist, militates in no degree against the grand fact that it is between the cranial vertebræ they all make their exit.

Having given the above general view of the composition of the osseous skeleton, a more difficult task now remains to be accomplished, viz. to identify and compare with each other the individual bones entering into the composition of the osseous system throughout the different vertebral classes, and thus to analyse the entire fabric. Various and conflicting indeed are the opinions of different writers on this important subject, of whose names and works an ample list will be given in the Bibliography affixed to the end of this article; but to enter into the argumentation of disputed points would of course be impossible in our prescribed limits. Suffice it to say, that the views of the acute and sound-judging Cuvier have been principally adhered to, and where occasion has been found to dissent from his opinion we have expressed our reasons for so doing.*

Bones of the cranium.—Frontals (1). These bones in fishes form the roof of the orbit and the anterior portion of the cranial box, having in front and behind them other pairs of bones forming the anterior and posterior boundaries of the orbit which correspond with the anterior and posterior frontals in Reptiles. In the *Frog* the whole of the anterior portion of the cranium is made up of a single bone, which entirely surrounds it like a ring or girdle, and represents the two frontal bones of Serpents

* We must here especially acknowledge our obligation to Professor Owen, who has most kindly placed at our disposal the result of his researches concerning the homology of the cranial bones of Fishes: his opinions have been introduced in their proper places.

(*fig.* 438, 1) united together. In the *Siren* and *Proteus*, however, the principal frontals are divided as in other Reptiles. In all Birds and Mammalia these bones become at an early period confused with the anterior and posterior frontals and ultimately with each other, so as to form but one piece, the *os frontis* of man; nevertheless, even in the human fœtus, they are separated by a suture which, in the lower Mammalia and also in the human subject, is not unfrequently persistent to a late period of life.

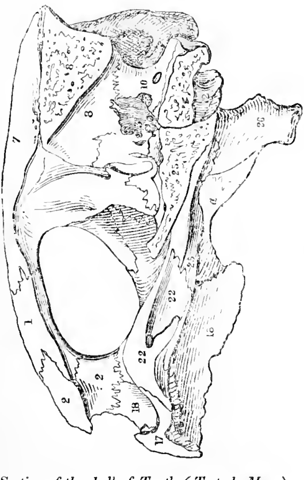
The *anterior frontals* (2) in the osseous Fishes bound the orbit anteriorly. Between these bones pass out the olfactory nerves, but they are not always distinctly recognisable, being occasionally permanently cartilaginous. In Reptiles these bones are generally distinct, but in Birds and Mammalia they coalesce with the preceding.

The *posterior frontals* (4) form the posterior margin of the orbit, and are present in Fishes and the Reptilia, but in Birds and Mammifers they are no longer recognisable as distinct bones.

The *parietal bones* (7) are placed behind the frontals; but these bones do not always touch each other, being separated, especially in Fishes, by the interposition of an azygos bone from which projects the occipital spine, which is frequently, more especially in Fishes, of very good size: this impair bone, the *interparietal* of some authors, is in reality the representative of the *superior occipitals* of Cuvier (*supra-occipitals*, Owen;) (8) and in some Fishes, especially in the *Siluri*, where the parietals are totally wanting, their place is supplied by the enormous developement of this element of the skeleton.

The *external occipitals* (9) contribute to form

Fig 440.



Section of the skull of Turtle (Testudo Myas).

the lateral portions of the occipital region of the skull, in conjunction with two other pieces called

The *lateral occipitals* (10), which partially bound the foramen magnum.

The *inferior occipital* or *basilar bone* (5) is that which invariably is articulated to the body of the first cervical vertebra, but occasionally in Fishes there are two additional articulations connecting the cranium to the spinal column formed by the lower portions of the lateral occipitals. All these elements of the so-called occipital bone of the human cranium remain permanently distinct in Fishes and Reptiles, and even in the fœtal condition of Birds and Mammals are more or less recognisable; but they soon coalesce into one large piece that enters largely into the formation of the cranial box, and constitute the first or occipital cranial vertebra, as has been already seen.

The *sphenoid* (6) invariably occupies the central portion of the base of the cranium, and in Fishes and Birds is prolonged anteriorly into a lengthy process which passes beneath the interorbital septum, which, in these classes of Vertebrata, remains most frequently membranous.

The *alar bones* (11; *ali-sphenoid*, Owen,) represented in the human subject by the greater alæ of the sphenoid, are in reality distinct elements of the cranium, and are recognizable by several important characters, especially by their position being joined by suture to the posterior frontral, and, conjointly with the latter bone, to the temporal. Moreover, through these bones the two posterior divisions of the fifth pair of nerves always pass out from the skull. In Fishes and Reptiles they are important pieces and quite detached from the sphenoid.

The squamo-temporal bones, Owen (*mastoid bones*, Cuv.: 12) in Fishes are manifestly the representatives of the bones so named in Reptiles. They contribute in conjunction with the posterior frontal, and occasionally with the alar, to furnish the articular surface that sustains the first bone of the palatine and tympanic apparatus, or, in other words, of the masto-temporal (23).

The *petro-temporal bones*, Owen, (13) are in Fishes placed between the mastoid, the lateral, occipital, and the alar bones. They are generally of small size, but occasionally, as in the *Gadidæ*, very largely developed, descending to reach the inferior occipital and the sphenoid. On the other hand, they are frequently entirely wanting, as, for instance, in the Pike, the Carp, and the Eel.

In all the Reptilia the petro-temporal bones are recognizable as distinct pieces forming part of the cranial box, and become interesting, inasmuch as it is in them that the auditory apparatus is lodged.

In Birds and Mammalia, however, the petrous bones become at an early period inseparably soldered to the other pieces, forming the so-called "temporal bone."

The *ingrassial bones* (14), as they have been named by Geoffroy, are, in the human subject, regarded as portions of the sphenoid, although in reality they are distinct elements of the skull. In the higher Vertebrata they are consolidated with the sphenoid, and have received the names of alæ minores or apophyses ingrassii. Above these pass out the olfactory and beneath them the optic nerves, a circumstance which in itself sufficiently indicates their real nature. Sometimes, as in the Carp, they are united together inferiorly, so as to form a roof over the optic nerves.

The *æthmoid*, Owen (*anterior sphenoid*, Cuv.: 15,) so highly developed in the carnivorous Mammalia, is in the lower Vertebrata reduced to an extremely simple condition. In Fishes (*fig.* 437) it is generally distinct enough, forming the posterior boundary of the interorbital septum, but sometimes it is quite wanting or represented by membrane. When present, it is generally placed upon the sphenoid, sending off processes to join sometimes the ingrassial bones, sometimes the alar bones, or occasionally to remain suspended in the interorbital membrane that unites all these parts. The œthmoid appears to be deficient throughout all tribes of Reptiles. In Birds it is recognizable as a bone of considerable size, separating the posterior parts of the orbits, which it assists in forming the two lateral facets that enter into the composition of those cavities corresponding with the *ossa plana*, as they are called, of the human subject; but these are obviously only portions of the œthmoid itself. In the Mammalia, owing to the prodigious developement of the olfactory apparatus, the *æthmoid* becomes extremely increased in size and importance, closing the anterior extremity of the cranial box, where it is perforated so as to present a central *crest* and cribriform plate, while inferiorly it has superadded to its body the *superior turbinated osseous lamellæ* that enter so largely into the construction of the olfactory organ.

The *vomer* (16) is in Fishes a large and important bone, joined posteriorly to the sphenoid and above to the œthmoid, forming a vertical portion, on each side of which are situated the organs of smell. Inferiorly it forms part of the roof of the mouth, and is often armed with teeth. Throughout all the Vertebrata this portion of the skeleton holds an analogous position and is recognized with facility. In Frogs and Lizards the bone is double, but in Tortoises and the higher animals generally there is but a single vomer, which enters more or less into the composition of the nasal septum.

The *nasal bones*, Owen; (*æthmoid*, Cuv.: 3) in Fishes are represented by a single bone impacted between the mid-frontals and the prefrontals, and inferiorly joined to the vomer, forming a kind of septum between the nasal organs, and thus in position resemble somewhat the vertical lamella of the œthmoid of Mammalia. Sometimes, as in the Eel and the Conger, the bones in question are inseparably united into one piece. In the higher animals the nasal bones are two in number, covering the nasal cavity like an arch. They are present in all Reptiles except the Chelonians, and in Birds and Mammals are easily recognizable from their position.

The *inferior turbinated bones*, although in consequence of the construction of their nose quite wanting in Fishes, must not be omitted in enumerating the elements composing the skull in higher animals. In the humbler Reptiles, indeed, no traces of it are distinguishable; but when the olfactory apparatus becomes fully developed, as in the Mammalia, they form an important part of the nasal character, and are found of large size, connected inseparably with the bones that surround the nose.

The bones of the face have been already considered as constituting a very complex framework, destined to lodge the organs of the principal senses or to constitute the instruments appropriated for the prehension or mastication of food. Seeing, however, that the same bone not unfrequently enters into the composition of several distinct cavities, we are unable to classify them further, and must therefore content ourselves with enumerating them *seriatim* as they occur to our notice.

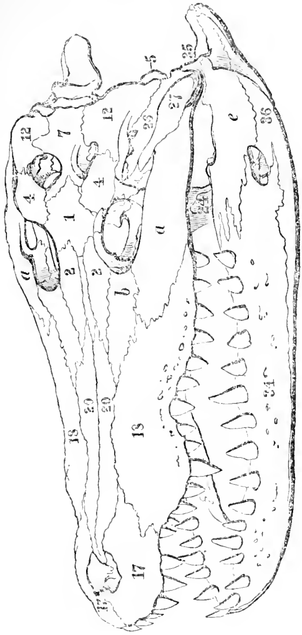
The *maxillary* (18) perform only a secondary office in forming the upper jaw of a Fish, being in the finny tribes generally destitute of teeth, which in them are principally implanted upon the intermaxillary (17) that form the greater portion of the upper jaw. The *maxillary* in Fishes is moveably articulated with the intermaxillary, the vomer (16), and the palatine (22). Sometimes, as in the Herring and Lepisosteus, this bone is divided into several pieces. In Skates and Rays the whole upper jaw is made up of a single ossified mass, which bears the numerous rows of teeth attached to its under surface.

But in all Reptiles, in Birds, and in Mammalia the maxillary bones form the principal portion of the upper jaw, more particularly in the Mammalia, where the intermaxillary bones are comparatively of small size. In this portion of the upper jaw are fixed the grinding teeth, where such are present, a circumstance which in itself demands great strength in this part of the face; and, consequently, wherever power of jaw is required to be conferred, it is principally obtained by the increased developement of this element of the skeleton, which thus becomes the largest and, as it were, the central bone of the whole fabric.

The *intermaxillary bones* (17) form the principal part of the upper jaw in Fishes, and upon their shape depends that of the snout. Sometimes these bones are flattened horizontally, or compressed laterally, or prolonged into a beak, their form being modified by circumstances in almost every genus. In the Chondropterygii, nevertheless, they are mere rudiments imbedded in the substance of the upper lip. They are persistent throughout all orders of Reptiles, Birds, and Mammals, until we arrive at the Quadrumana, where they become anchylosed with the maxillary, and in Man they are quite obliterated at an early period.

The bones of the face in osseous Fishes are exceedingly numerous and irregular, neither is it easy to identify many of them as being at all analogous to those which normally make up the face, even of those Reptiles which present

Fig. 441.



Skull of the Crocodile of the Nile.

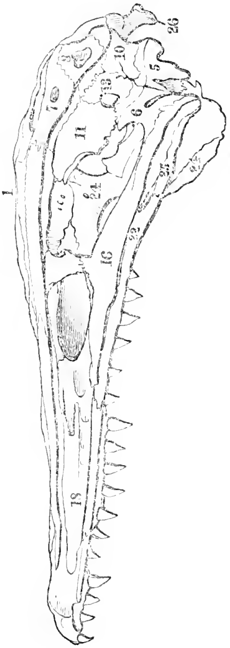
the most complicated condition of this portion of the skeleton. The higher cartilaginous Fishes, however, (*Chondropterygii,*) form a very remarkable exception; for in the *Rays* and *Sharks* the face is reduced to a very simple condition, in consequence of the want of separation between the different pieces of the skeleton, consequent on the permanently cartilaginous state of the osseous system in these tribes.

The *suborbital bones* in Fishes (*fig.* 437, *g*, *g*, *g*, *g*) form a kind of chain composed of a very variable number of pieces which surround the inferior and external margin of the orbit, covering the muscles of the face instead of giving attachment to them, a circumstance which induced Cuvier to believe that they did not normally belong to the series of facial bones. They are doubtless referable to the exo-skeleton or cuticular bones so largely developed in some fishes, and in this light they will be considered in another place.

The *prænasal bones*, Owen; (*nasal bones*, Cuv.) of a Fish (*fig.* 436, 20) are found in a situation very analogous to that which they occupy in the higher Vertebrata. They form the internal boundaries of the nasal chamber, and articulate superiorly with the frontal (1). These bones are regarded by Professor Owen as being the representatives of the moveable cartilages of the nose of other Vertebrata ossified and entering into the composition of the facial skeleton.

Besides the suborbital chain of bones (*g*,*g*,*g*,*g*) above mentioned as partially surrounding the orbit, and which in the Gurnards and other hard-cheeked Fishes cover the cheeks as with a bony case, entitling them to the name applied to them by Cuvier of "joues cuirassés," another chain of bones called the *supra-temporal* is not unfrequently met with, placed on each side, over the interval that separates the external from the middle prominent ridge, developed from the exterior of the cranium so as, together with these projections, to cover the articulation of the supra-scapular bone (46). These bones are evidently peculiar to Fishes, and, like the suborbital, must be referred to the exoskeleton and not deemed to belong properly to the osseous system. In this light they will be considered in another place.

Fig. 442.



Section of Crocodile's skull.

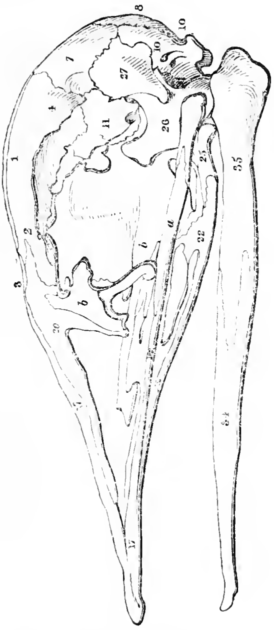
The palatine arch or osseous roof of the mouth is composed of analogous bones in all the different races of Vertebrata; but in the lower Vertebrata there are found in connection with this region of the skeleton several pieces that have no representatives in the higher classes.

The *palatine bones* (22) are easily recognisable in Fishes, occupying the same place as in Serpents (*fig.* 439), and, moreover, further distinguished by being frequently armed with teeth which project into the roof of the mouth. In Reptiles, also, teeth are often attached to them where they assist in forming the cavity of the mouth. These bones are found in all the vertebrate classes.

The *transverse bones* (24) occupy nearly the same situation in Fishes as in Reptiles, but in the latter they are most distinctly seen. In the Crocodile each is a bone of considerable size, composed of three branches and extending between the pterygoid bone and the junction of the jugal, the maxillary, and the posterior frontal. This bone is not met with, either in Birds or Mammalia, not even in the fœtal period of their existence.

The *internal pterygoid bones* (25) are likewise distinct in fishes, stretching between the

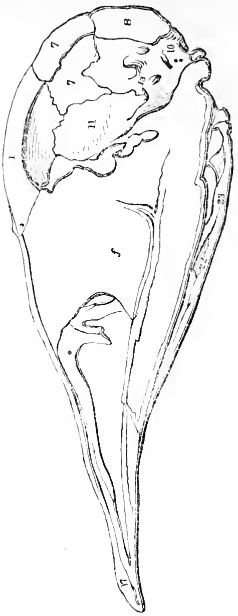
Fig. 443.



Skull of a young Ostrich (Struthio Camelus).

palatine bone and that which supports the lower jaw (26). In Reptiles they are large and important detached bones, occupying the position of the pterygoid processes of the sphenoid; but in Birds and Mammals they become completely anchylosed with the sphenoid, so that, by the human osteologist, they are erroneously regarded as apophyses of that bone.

Fig. 444.



Section of skull of young Ostrich.

The *zygomatic*, Owen, (*jugal*, Cuvier,) are in Fishes broad pieces, generally of a triangular shape, placed behind the transverse, which by their inferior angle support the articulation of the lower jaw. In Reptiles, too, it may always be distinguished by the latter circumstance, and in Serpents it is particularly remarkable (*figs.* 438, 439, 26), standing out from the squamo-temporal (*mastoid*, Cuv.) like a branch, and thus giving that extraordinary mobility to the articulation of the inferior maxilla which enables those Reptiles to swallow prey so disproportioned to the size of their mouths. In other Reptiles this mobility is in a great degree lost. But in Birds the zygomatic bones again assume very important functions. They are here known by the name *ossa quadrata*, and standing out to a considerable distance from the skull allow of great mobility to the zygomato-maxillary articulation, and also to the bones supporting the superior maxilla. In Mammalia this zygomatic bone is so firmly and undistinguishably united to the temporal that the human osteologist merely calls it the zygomatic process of that bone.

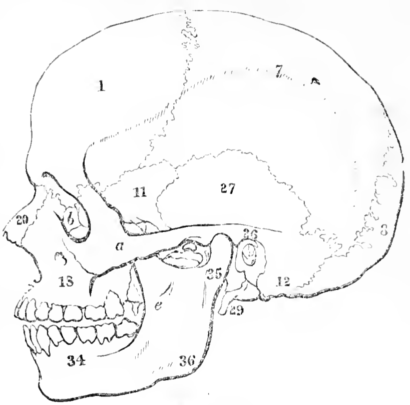
The *masto-temporal*, Owen, (*temporal*, Cuv 23), are in Fishes and Reptiles distinct elements of the skull, which in the human cranium are consolidated with the other elements composing the "*os temporis*."

The *styloid bones* (29), mere rudiments in the human skeleton, anchylosed with the rest of the temporal bone, of which they are called the "styloid process," in the water-breathing Vertebrata are distinct pieces interposed between the os hyoides and the base of the skull, serving to unite the former to the latter.

The *symplectic bones* (31) seem to be peculiar to Fishes; they accompany the transverse, and assist in connecting the articulation of the lower jaw with the pterygo-palatine apparatus.

The *lower jaw*, although in the adult human subject formed of a single piece, in the *fœtus* consists of two lateral halves united by a symphysis, as it is permanently in many of the lower Quadrupeds. In Reptiles and Fishes, however, each half consists of numerous pieces, to which distinct names have been given by the comparative anatomist. In the Crocodile and most reptiles there are six in number, viz. the *dental portion* (34), in which are situated all the alveoli of the teeth, uniting with its fellow to form the symphysis of the jaw.

Fig. 445.



Human Skull.

The *opercular*, covering almost all the inner aspect of the jaw except in front.

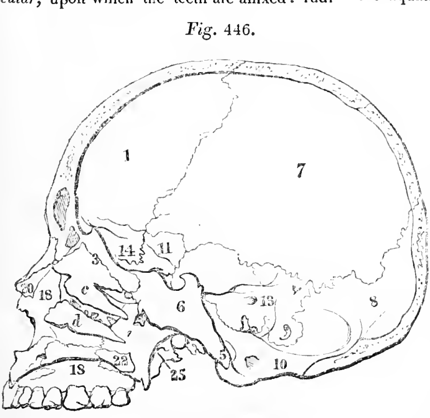
The *angular* (36) and the supra-angular (35), placed one above the other, reaching quite to the posterior extremity of the jaw. In the Crocodile they leave between them a considerable space occupied anteriorly by the end of the dental portion, and then by a large oval aperture.

The *articular* (*e*), bearing the articular process, whereby the jaw is connected with the skull. Likewise another small and unimportant plate of bone sometimes seen on the inner aspect of the inferior maxilla.

In the Chondropterygious Fishes the lower jaw is made up of only one bone, the *articular*, upon which the teeth are affixed: rudiments of the others are, however, met with imbedded in the flesh beneath the skin.

The hyo-branchial apparatus.—The osseous framework to which in the human subject the name of *os hyoides* has been appropriated, from the trivial circumstance that in the simple condition under which it presents itself in man it resembles the Greek letter υ, is found in the lower Vertebrata to be permanently composed of very numerous pieces, which are made subservient to respiration, and from their size and number render the whole apparatus, which they assist in forming, really worthy of the name of an anterior thorax. The hyoid system of bones may indeed be regarded as being in some respects vicarious in function with the true thorax, the former belonging especially to the aquatic, the other to the aerial mode of respiration; whilst, therefore, as in Fishes, the gills form the only means of breathing, and the branchial arches exist in their full state of developement, the hyo-branchial apparatus is complete and preponderates in importance over the thorax; but, in proportion as pulmonary respiration is established, as we ascend the scale of animal existence, the thoracic system of bones assumes the principal duties connected with the inspiration and expiration of air, and the os hyoides dwindles into a very rudimentary condition. The above circumstances however, interesting as they are when a mere comparison is instituted between the hyoid bones of various animals as to their composition when in the adult state, assume additional importance when we reflect that all the higher Vertebrata possess in the earlier stages

Fig. 446.



Human Skull.

of their life a true branchial apparatus, which subsequently becomes absorbed to give place to thoracic or pulmonary respiration, and consequently they are furnished in the first portion of their existence with the hyoid system of a fish, which, passing through different phases of gradually diminishing complexity, is slowly converted into the simple form it presents in their mature or adult condition. So diversified, in fact, is this portion of the osseous skeleton in the different classes of Vertebrata, that the anatomist only acquainted with human osteology would never be able to recognise the analogy between what he sees in man and the condition in which it exists in its more complicated states, or at all understand the metamorphosis which it undergoes in the embryo of Mammalia, without tracing it through all its forms, as we shall now proceed to do with as much brevity as is compatible with our subject.

In the Fish the os hyoides is situated as in all the other Vertebrata, and is composed of twelve bones. It consists of two branches, each made up of five distinct elements, namely, the styloid bone (29), which suspends it to the temporal; two broad lateral pieces (*fig.* 436, 37 and 38) placed one behind the other, and two small bones (39 and 40) placed one above the other at the anterior extremity of each branch, and forming with their fellows of the opposite side a kind of symphysis uniting the two halves of the bone. In front of this symphysis is a single bone, the *lingual* (41) situated as in Birds and Reptiles, and behind in the angle formed by the union of the two branches another azygos piece representing the *tail of the os hyoides* so distinct in Lizards and in Birds. This latter piece becoming joined to the symphysis of the humeral bones forms the isthmus that inferiorly separates the two branchial apertures of the fish.

Appended to the inferior and external margin of each branch of the os hyoides of a fish, are the *branchiostegous rays* (*fig.* 437, 43), destined to support the branchiostegous membrane that completes the gill-covers. These are very various both in number and form in different fishes; they are fixed to the os hyoides by distinct articulations, sometimes by simple ligaments. Autenrieth and Geoffroy suppose these branchiostegous rays to be the representatives of sternal ribs, but doubtless they belong rather to the exo-skeleton.

To facilitate, however, a comparison between the above complicated series of bones and the corresponding pieces met with in other classes, it will be advisable to lay before the reader the result of the elaborate analysis of this part of the skeleton made by Geoffroy St. Hilaire, whose names applied to the various elements composing it are not only classically elegant, but from their simplicity will save much useless circumlocution. When complete, the distinguished anatomist alluded to considers the o hyoides to consist of the following parts: The body or *basihyal* piece, forming the central portion of the fabric; the *urohyal* or *tail* of the os hyoides (*fig.* 437, 42); the *entohyal*, a piece sometimes interposed between the two former; two *glossohyals* or posterior cornua; two *apohyals* (39) forming the first pieces of the anterior or styloid cornua; two ceratohyals (40) forming the second pieces of these branches; and lastly, two stylohyals (29), which are represented in the human subject by the styloid processes of the temporal bone.

Appended to this hyoid apparatus are a series of lateral arches emulating in their importance the ribs in the water-breathing Vertebrata, and indeed somewhat resembling them in structure and arrangement, along which run the branchial vessels to the gills, and subsequently from the gills to form the aorta. These arches have in fact, by some continental anatomists, been actually looked upon as representing the thorax of Vertebrata that respire the air, but with little reason, as must be evident on considering how, as the real thorax is called into play, these are gradually absorbed and disappear.

The *branchial arches* of a fish, from which are suspended the branchial fringes, consist on each side of four chains of bones adherent by their inferior extremities to an intermediate series of ossicles, which is connected anteriorly with the symphysis of the os hyoides between the four anterior elements of that bone and above its *tail*. Superiorly the branchial arches are fixed by a ligamentous attachment beneath the cranium.

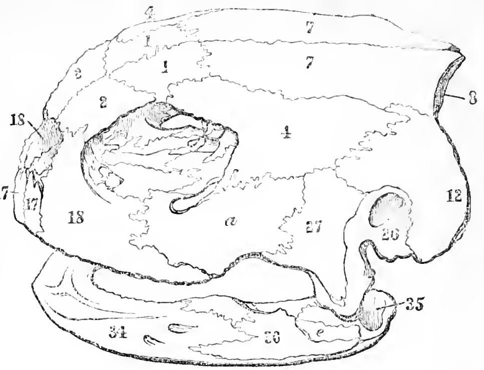
The series of intermediate bones with which the pairs of branchial arches are connected inferiorly, are placed behind the lingual and are three in number, forming a kind of little sternum to the hyoid apparatus. Each of the branchial arches consists of a superior and inferior portion that are moveable upon each other. The inferior portion (*fig.* 437, 58) is that connected with the intermediate chain of bones, and in the anterior three pairs of arches this is formed of two pieces. The posterior pair has this part composed of only one piece. The upper portions of the branchial arches are made up of a single bone. The three posterior (*fig.* 437, 61) support the *pharyngeal bones* (*fig.* 437, 62), while the anterior is attached to the skull by the intervention of a little style (59), which might be regarded as the pharyngeal bone belonging to this pair.

Internally all the branchial arches are provided with osseous plates or ridges which are generally covered with teeth. These perform in some degree the function of the epiglottis of Mammalia, inasmuch as they prevent anything taken into the mouth from getting into the gills along with the water as it passes to the respiratory organs.

The *pharyngeal bones* are peculiar to Fishes, and are situated in the throat, where they powerfully assist in masticating the food. There are usually two inferior and six superior. The inferior (*fig.* 437, 56) are attached behind the branchiæ in the angle formed by the last pair of branchial arches; they are generally of a triangular shape, and form a kind of floor to the pharynx. The upper pieces (*fig.* 437, 62) are three in number on each side, each attached to the extremity of the upper portion of one of the three last branchial arches.

Condition of the os hyoides in Reptiles.—The condition of the os hyoides in a perfect Reptile is very simple when compared with that of the Fish, or even, as is most strikingly apparent in the amphibious Reptilia, with that which it exhibits previous to the accomplishment of the metamorphosis which changes the mode of respiration from that of a fish into that of the Frog. In the adult Reptile, indeed, the composition of this bone gives no indication of its previous complexity of structure, consisting only of the remains of the anterior cornua (26, *a*) and a broad hatchet-shaped disc forming the body of the bone. In Lizards its structure remains more complicated, resembling that of Birds. The body is generally simple, with two and sometimes three sets of cornua-like appendages connected with it. From the fore part of the body projects a long and slender process, more or less cartilaginous, which penetrates the substance of the tongue. The anterior pair of cornua are variously folded, and the posterior placed differently in different genera; while the third pair, which is but seldom met with, seem rather to be prolongations of the body of the bone than separate elements appended to it. In the Chelonian Reptiles the hyoid apparatus varies remarkably in form in different species. It generally consists of a central part, which is frequently itself divisible into several pieces, and of two or sometimes three pairs of cornua. Moreover, beneath the anterior part of the body, there is suspended a bone or cartilage, which is sometimes double and represents the special bone of the tongue, which in Birds is articulated to the fore part of the body of the os hyoides.

Fig. 447.



The *os hyoides* of the Crocodiles is the simplest met with in the class of Reptiles, its central portion being a mere broad cartilaginous plate, convex below, concave above; its anterior part having a semicircular form, while its posterior margin is hollowed out into a concave edge; there are no remnants of cornua visible, and the os hyoides here seems to perform the duties of epiglottis, hyoid, and thyroid cartilage.

Metamorphosis of the os hyoides.—Professor Bell having already described the most remarkable changes which the branchial apparatus of the Frog undergoes during its metamorphosis, it would have been needless to recur to the subject again in this place, were it not for the purpose of collating the facts there recorded with the series of changes we are now discussing, and indicating the nature of the respective bones delineated in a preceding volume (vide Article Amphibia, vol. i. *figs.* 21, 22, 23, 24, 25, 26). We shall, however, embrace the opportunity afforded of adding a few circumstances to those there recorded, extracted from the observations of M. Martin St. Ange, connected with this most remarkable and interesting process.

Some days before the birth of the Tadpole the os hyoides consists of a single median piece, of a pair of broad cartilaginous plates situated on each side of the former, anteriorly, and of two other similar plates occupying a like position behind, to each of which last are appended four separate styliform pieces representing the branchial arches, making thirteen pieces in all.

Examined a little after birth, the whole cartilaginous frame-work is found to have increased considerably in breadth, more espscially the eight last-mentioned cartilaginous styles upon which the branchial vessels run, sufficiently indicating their nature—moreover, they become united together by their distal extremities so as to form a series of arches, as represented in *fig.* 21, vol. i. p. 98, at *c*. At this point of its developement the hyoid system of the Frog is at its maximum of complexity, and we will therefore pause to examine the elements that enter into its composition. The median piece (*fig.* 21, *b*, vol. i. p. 98) represents, according to Geoffroy, the *glossohyal*, *basihyal*, and *urohyal* elements of the Fish. The elements marked *a* will be the *stylhyal* bone, suspending the whole from the tympanic bone of the skull (*e*), while the broad pieces *c*, *c*, regarded by the same author as being dismemberments of the larynx, immediately sustain the branchial arches.

At that period, when in consequence of the changes that take place in the circulation of the Tadpole the branchial vessels are to be obliterated, the condition of the os hyoides too becomes rapidly changed. The cartilaginous arches become diminished, especially in length, and at last become completely absorbed excepting two remnants, which are found appended to the posterior margin of the os hyoides even in the adult Frog, although they remain for a very long while in a cartilaginous condition. The two pieces *a*, *a*, then speedily become diminished in breadth, and the whole shape of the os hyoides approximates that of the adult Frog, the condition of the pieces marked *a*, *a*, forming the chief difference between them. This at length becomes gradually more slender and elongated, assuming at last the shape delineated in *fig*. 26, vol. i. *(a)*, where the permanent and complete condition of the os hyoides of this Reptile is fully established.

The different pieces composing the os hyoides of a Bird having been already described and figured (vide Article AVES, *fig*. 151), it only remains for us in this place to complete our review of the hyoid apparatus by examining its condition in the Mammiferous races, in which it is found gradually to become stripped of many parts that before entered so conspicuously into the construction of this portion of the osseous frame-work of the throat, and assume a simplicity of structure that progressively assimilates to the shape it presents in the human subject, in which alone indeed the name of *hyoides* is at all applicable. In Man, observes Geoffroy, the os hyoides is generally said to consist of a body and four symmetric pairs of branches or cornua. The anterior cornua (superior when man stands in the erect posture) are reduced to mere rudiments, but in those Mammalia that have the head elongated these anterior cornua are very largely developed, appended from the sides of a special pair of bones, the *styloids*, which, although in mankind they are reduced to simple and almost useless apophyses, consolidated with the temporal bones in the generality of Mammifers, are very large and important pieces, so connected with the anterior cornua that they are frequently regarded as being additional parts of the os hyoides. But although in the human body these apophyses are comparatively small, and are respectively removed, as it were, to their proper places, the *styloids* to the cranial bones, and the anterior cornua to the os hyoides, they perform the same office of connecting the hyoid apparatus to the cranium in Man by the interposition of a cartilage, and in quadrupeds still more effectually by an uninterrupted chain of bones connected with each other.

The *posterior cornua*, each consisting of a single piece, resemble each other in office at least, in all the Mammalia, forming with the *body* of the os hyoides a horse-shoe figure, to which the larynx is appended. The body itself, or central portion of the bone, although in the human subject only represented by a slight tuberosity, will be found in the Rodentia, Ruminants, and more especially Solipeds, to become very conspicuous, and in the last case obviously distinct elements of the skeleton. In these Mammalia indeed, the os hyoides is found to consist of no fewer than nine pieces, without enumerating the styloid bones; a condition of complexity almost approaching that met with in the Birds and inferior Vertebrata.

Leaving the consideration of the bones of the face, and those which enter into the composition of the hyo-branchial apparatus, which may be all regarded as forming a succession of arches depending from the sides of the cranial vertebræ, of the transverse processes, of which they are indeed regarded by some writers to be real costal prolongations; the anatomist finds a more or less extensive series of bones derived from the sides of the spinal vertebræ, and frequently arching downwards to enclose and protect the viscera either of the thorax or of the abdomen, or of both. These lateral appendages to the spinal column are invariably in connection with the transverse processes, of which in their simple forms they might seem to be derivations, but when largely developed, as for example in the thorax of Mammiferous animals, they attain to a prodigious size, forming, almost by themselves, the frame-work of the thorax, and constituting the principal agents employed in the performance of the mechanical actions connected with the inspiration and expiration of the air used for the purpose of respiration. The position of the ribs thus employed for the formation of a thorax is extremely variable in different races. In Man and all other Mammalia, in obedience to a law at present unexplained, they commence invariably at the eighth spinal vertebra, counting from the skull; but in Birds the whole thorax is removed much further backwards in order to allow of the greater elongation of the neck.

Besides the dorsal ribs thus derived from the spine, and which exist alone in the human subject and in Mammalia generally, another series of additional elements is met with in Reptiles and in Birds, which must be called *sternal* ribs, and these, conjoined with the last, enter into the composition of the thoracic cavity. In Fishes only dorsal ribs are met with, and these are connected by a simple articulating facet to the sides of the bodies of the vertebræ placed immediately above the abdominal cavity. Frequently, however, the ribs of Fishes have supplementary bones appended to them, which in the living fish are embedded amongst the lateral muscles of the body. Sometimes, indeed, these additional rib-like processes arise immediately from the bodies of the vertebræ themselves, giving an appearance of complexity to this portion of the skeleton that is calculated to puzzle the young osteologist. In the Cyprinidæ and the Herring tribe a small osseous piece is interposed between the vertebra and the rib that is appended to it; this is obviously a detached transverse process. In the Batrachia dorsal ribs only are found, and these, even when most largely developed, are mere rudiments appended to the ends of the transverse processes of the vertebræ.

In Serpents likewise the enormously prolonged thorax is entirely made up of dorsal elements, but these, existing as they do almost along the whole length of the body, and being moved by an elaborate muscular apparatus, perform to a certain extent the office of locomotive organs.

In the Chelonian and Saurian Reptiles the construction of the thorax becomes much more complicated by the developement of additional elements hereafter to be described, and in these tribes the examination of the dorsal ribs exhibits to the osteologist several points of very great interest relative to this portion of the skeleton. In the Crocodile, for example, the elements derived from the vertebræ present every gradation of form between the simplest and most complex condition of the costal pieces. The hinder ones are loose and floating, being mere appendages to the transverse processes, to the ends of which they are fixed as in the Batrachia, by a simple undivided articulation; but as we advance forwards from this point along the true thorax, their connection with the vertebræ becomes progressively changed through a series of most beautiful gradations of form; the head of the rib becomes slowly divided into two distinct articulating surfaces, both of which are at first attached to the transverse process of the corresponding vertebra, but more anteriorly the bifurcation of the head of the rib being completed, one division becomes attached to the body of the vertebra, while the other, the *tubercle*, is fixed to the transverse process, and every gradation intermediate between the two extremes of structure presented in this portion of the skeleton is thus exhibited in the same animal. But dorsal ribs are developed in the Crocodile anterior to the thorax and with a very different office, costal appendages (*fig.* 432, *o*) being attached to all the transverse processes of the cervical vertebræ. These, instead of being prolonged downwards, spread out anteriorly and posteriorly, assuming the shape of the letter T, and forming a continuous chain of bones, that trammels the lateral movements of the neck, but at the same time affords ample surface for the attachment of the unusually strong muscles of this Reptile's neck. The dorsal ribs of the *Chelonian* Reptiles are equally interesting on account of the strange modification in the manner of their connection with the spine, whereby they are absolutely brought quite to the exterior of the body, and in the Tortoises so completely united by suture to the spinous processes of the vertebræ, and likewise to each other, as to form the greater portion of the dorsal shield or carapax peculiar to these races. In order to effect this total change in the position of the costal elements of the skeleton, the anatomist finds to his astonishment that very simple arrangements are necessary. The neuro-spinal apophyses of the vertebræ are prodigiously developed and spread out into broad flat osseous plates firmly connected with each other and with the tubercles of the ribs by means of their broad serrated margins; this being accomplished, the usual attachments between the head of the rib and the spine become unnecessary; the bodies of the vertebræ remain quite rudimentary, the transverse processes are obliterated, and the head of the rib itself reduced to a ligamentous condition, the carapax being left sufficiently strong without any necessity for the usual abutments of the ribs on the vertebral column.

In Birds, on the contrary, a precisely opposite arrangement is required in order to combine strength and lightness in the construction of the framework of their thorax, which must bear the strain of the strong muscles used in flight. The bifurcation of the commencement of the rib is here exaggerated to the utmost; its strongly developed head is firmly articulated to the vertebral bodies, and by means of its tubercle it is additionally secured to the transverse processes of the dorsal vertebræ, and moreover, besides the strong buttresses thus made to sustain the thorax, additional long splints of bone project backwards from the dorsal ribs much in the same manner as in Fishes, only here the superadded processes are prolonged until they overlap the rib succeeding next behind, binding the whole together; and materially assisting to strengthen the thoracic framework.

But even in Birds, as in the Crocodile, the dorsal ribs are found developed from the vertebræ anterior to as well as behind the proper thorax.

In Mammals, the great portion of the chest consists of dorsal ribs, which are eked out in front by costal cartilages connecting them on each side to the sternum. Yet still the floating ribs behind the proper thorax are persistent, and in one rare instance, namely, the Sloth, they exist in front as well, appended to what else the anatomist would call cervical vertebræ. We therefore see at once that the division of the spine into the different regions pointed out in the human skeleton is quite arbitrary, as the existence of ribs and the possession of a thorax are by no means necessarily linked together.

A very singular illustration of the co-existence of thoracic and non-thoracic ribs is met with in Reptiles belonging to the remarkable genus *Draco*, in which, although the anterior ribs are completely developed so as to form a true chest, the six hinder pairs are converted to a totally different use, being prolonged laterally to a great extent, and covered with a duplicature of the integument so as to form an ample parachute, by the assistance of which these agile little lizards are in some degree supported in the air as they leap from branch to branch.

The thoracic portion of the skeleton is only met with in a complete state in Birds and the higher Reptilia, the Saurians and Chelonians, in which races it constitutes a very elaborate framework composed of numerous elements, of which no traces are perceptible in the human subject or in the generality of Mammalia. In the Crocodile it is seen to be made up of the following parts—1st, of a complete apparatus of *dorsal ribs* (*fig.* 432, *l*), connected to the transverse processes and bodies of the dorsal vertebræ; 2ndly, of an equal number of *sternal ribs* (*m*), interposed between the ends of the former and the sides of the sternum; and, 3dly, of the *sternum* (*n*), forming the pectoral boundary of the chest.

The sternum itself, although usually considered by the human osteologist as being extremely simple in its composition, is, when fully developed, made up of several distinct elements equalizing in importance any that assist in building up the skeleton. It is, however, only in the Chelonian Reptiles that the sternal bones present themselves in full completeness, forming the broad shield or *plastron* that defends the ventral aspect of the body in those animals, which, being solidly connected on each side with the dorsal plate or carapax, forms a kind of box to shelter the whole body.

The sternum, thus necessarily amplified to the utmost, consists of no fewer than nine distinct elements, to all of which names have been applied expressive of their position relative to each other. First, there is an azygos element occupying the mesial or central portion of the anterior part of the plastron, which from its situation has been named the *entosternal* element. This central piece is bounded anteriorly by the *episternal* bones, and posteriorly by another pair named the *hyosternal*, being as it were set in the centre of these lateral pieces as in a frame. The posterior half of the sternum consists of two pairs of elements, the larger and most anterior being designated as the *hyposternal*, whilst the posterior occupying the position of the xiphoid cartilage in the human skeleton are fitly denominated the *xiphosternal* pieces, which are united to each other and to the last-mentioned pair by strong serrated sutures, as indeed are all the elements above enumerated.

In the aquatic Chelonians, the *Turtles*, the same elements are met with entering into the formation of the enormous sternnm, and their positions with respect to each other are precisely similar; but here, in order to lighten the skeleton, large excavations are hollowed out in the centre of the bone, so that the three posterior pairs of sternal elements do not meet in the mesian line; but in all other respects their identity is at once evident. The sternal apparatus, however, although most frequently it enters largely into the formation of the thorax, is still more nearly related to the anterior extremity, with the movements of which it is invariably intimately connected, and frequently gives origin to the most important muscles of locomotion. The sternum can scarcely be said to exist in Fishes, with the exception of a very few (*Clupea*), and in these it is represented by a few azygos bones, on which the ribs abut inferiorly.

In the Anourous Batrachia, as the Frog and Toad, the sternum is remarkable as existing in a very complete state of developement quite independently of any other elements of the thorax, seeing that in these animals there are no ribs to be attached to it. It consists here of a chain of bones, in which most of the elements above enumerated are easily recognizable, placed along the mesian line of the breast, and supporting on either side the coracoid and clavicular bones that enter into the composition of the shoulder; the whole apparatus has been already figured in the article Amphibia, (*fig.* 17,) where the episternal bones forming the most anterior part of the series, the *hyosternal* bones (*e*), the *entosternal* bone (*g*), to the sides of which are attached both the clavicle (*c*) and the coracoid (*d*), the *hyposternal* bones (*f*), and the *xiphisternal* elements completing the chain posteriorly, are all indicated.

The sternum of Birds is peculiar on account of the prodigious developement of the azygos or *entosternal* element of which it is principally composed, a circumstance obviously intended to strengthen this part of the skeleton, and prevent the tearing asunder of the lateral portions of the bone by the enormous strain of the strong and massive muscles of flight, an accident of which there would have been great danger had the mesial sutures that exist in the sternum of the Tortoise been here permitted. The pieces composing it are pointed out in *fig.* 129, vol. i. p. 282, where the following elements are delineated, viz. the *entosternal* (*a*), the *hyosternals* (*b*), the *hyposternals* (*c*), and the *xiphisternals* (*g*).

The sternum of Mammalia becomes once more reduced to its simplest form, consisting of a chain of osseous pieces situated along the mesian line on the anterior aspect of the thorax, which they partially assist in forming. In some races, however, as, for example, in the Monotremata, so closely allied to Birds in all the details of their economy, and also in Quadrupeds possessing great power of using the anterior extremities either for flight or digging, as, for example, the Bat and the Mole, the importance of this part of the osseous framework becomes considerably increased, and it is developed accordingly.

Frequently connected with the sternum, but by no means to be regarded as derivations from that bone, are the other important elements of this part of the skeleton already noticed, which, though entirely deficient in the human subject and in the Mammalia generally, are found in Birds and many Reptiles to be essential to the structure of the thorax. These are the *sternal or abdominal ribs* (*fig.* 432, *m*) a series of distinct bones interposed between the spinal ribs and the sides of the sternum, so as to form a complete osseous framework to the chest. In Fishes, as well as in the Batrachian and Ophidian Reptiles, these bones are absolutely wanting, though in the *Frogs* and *Toads* the sternum is so large. But in the Saurians, as, for instance, in the Crocodile, they form essential parts of the thoracic cavity, and aid materially the movements requisite for respiration. In the Crocodile these ventral ribs extend indeed much further backwards than the dorsal ones that form the posterior boundaries of the thorax, being continued along the abdomen almost as far back as the pelvis imbedded in the abdominal muscles, the action of which they doubtless materially strengthen.

In the higher Vertebrata, i.e. the Mammalia, the sternal ribs are entirely represented by the costal cartilages, and the abdominal would seem to be completely wanting; still there seems but little doubt that, even in Man, the lingering rudiments of ventral ribs are traceable in the tendinous intersections of the recti muscles of the abdomen.

In Birds the sternal ribs assume still more importance as regards their effect in strengthening the thorax, and converting the thoracic portion of the skeleton into an osseous framework able to sustain the stress of those powerful muscles that wield the instruments of flight. At one end each of these pieces is moveably articulated with the distal extremity of the corresponding dorsal rib, whilst at the opposite it is firmly attached to the sides of the expanded sternum by joints that admit of a certain extent of motion.

It is in the Chelonian Reptiles that these accessory portions of the thorax attain their greatest growth, spreading into broad plates that are connected by strong sutures to the extremities of all the spinal ribs and likewise to each other in the Tortoises, completing thus the carapax or dorsal shield; and, moreover, being solidly united at the sides with the enormous apparatus of sternal bones, the whole body of the Tortoise becomes encased in bony armour, derived entirely from the thoracic elements of the skeleton.

The ANTERIOR LIMBS of Vertebrate animals, although essentially composed of similar elements throughout all the classes belonging to this great division of animated nature, are made subservient to very various and opposite uses; the pectoral fin of the Flying Fish, the enormous hand of the Skate, the paddle of the Turtle, the flipper of the Whale, the wings of the Bird and of the Bat, the broad shovels of the Mole, and that masterpiece of organization, the human hand, being respectively but simple modifications of the same structure.

In the osseous Fishes, indeed, it is not always easy to recognise the elements that are correlative with those of the higher Vertebrata; but a little attention is sufficient to prove the construction of the pectoral fins among the finny tribes to be true representatives of the anterior extremities of other races, as will be evident from the following masterly analysis of the parts composing the pectoral fin of the Perch, given in Cuvier's great work on Fishes. Immediately behind the gill-openings there is placed on each side a framework of bones that bound the branchial apertures. This frame is attached superiorly to the back of the head, but inferiorly the two halves are united together, forming a bony zone that surrounds the body at this part; and being connected inferiorly with the body of the os hyoides, forms here a kind of isthmus that separates the gill-openings from each other. The bony zone above described is made up on each side of three pieces, which represent the bones of the shoulder and of the arm, to which is affixed posteriorly a group of two or three other bones that represent the forearm, wherewith is connected the fin itself, the representative of the hand. The names applicable to these pieces of the skeleton when their analogies are strictly investigated are as follow:—The *suprascapular*,* the *scapular*,† the *humerus*,‡ the *radius* and *ulna*, to which succeed the *carpal bones* and the *phalanges* of the fin. In addition to these must be noticed the two pieces regarded by Cuvier as representing the coracoid bone of Reptiles.

When fully developed, the anterior extremity is made up of a greater number of elements than exist in the human skeleton. The shoulder is a strong framework, composed of three distinct pieces, named respectively the *scapula*, the *clavicle*, and the *coracoid bone*. The other bones of the limb resemble each other in their general arrangement throughout all the Vertebrata, and in the Crocodile, where all parts of the limb present a medium state of developement, the analogies between the bones composing it and those of the human arm are at once recognised. The *humerus*, a single bone, supports the first division of the limb. Two bones, the *radius* and the *ulna*, are met with in the forearm, while the bones of the *carpus*, the *metacarpus*, and the phalanges of the fingers present an arrangement similar to what is found in the human body. In order, however, to appreciate the important modifications required in the disposition and conformation of these elements in the different races possessing them, it will be needful to examine them successively in the order in which they have been enumerated.

The *scapula* is the most important piece entering into the composition of the shoulder, and not unfrequently, among the Mammiferous races, is the only bone developed for the support of the anterior limb. In Reptiles and in Birds, where so great freedom of motion as is required in terrestrial Quadrupeds would be inadmissible, the movements of this part of the skeleton are considerably restricted, and a kind of anterior pelvis formed which gives great strength and firmness to this part of the skeleton. The scapulæ are generally laid like splints along the exterior of the chest, in which position they are, as it were, suspended by strong muscles; but frequently this arrangement is necessarily departed from for obvious reasons. In the Batrachia, for example, such as the *Frog* and the *Toad*, the ribs are altogether wanting, and the strength of the shoulder must consequently be provided for in a peculiar manner. The *scapulæ* are enormously developed so as to perform, to a certain extent, the office of ribs; and, moreover, each being divided, as in Fishes, into two portions, united by cartilage to each other, the strength and resiliency of a chest is in some measure obtained. It is, however, in the Chelonian Reptiles that the most extraordinary deviation from the usual arrangement is witnessed, where the scapulæ are absolutely placed in the interior of the thorax, where they are connected by one extremity to the sides of the bodies of the dorsal vertebræ.

No spine or acromial process exists in the scapulæ of the oviparous Vertebrata, and even in the quadrupedal Mammals these parts of the bone are very imperfectly developed when compared with their condition in Man, in whom alone they assume their full importance.

The *clavicle* forms the second element em-

* Synonyms — *Omoplate*, *Omolite*, *Pedicule de l'epaule*.

† Syn.—*Omoplate* (Geoffroy), *Acromion* (Bakker).

‡ Syn.—Clavicle (Meckel, Geoff.), *Cœnosteon* (Bakker).

ployed in constructing the shoulder-joint, but is by no means constantly present. In Fishes its existence as a distinct bone is not recognisable; but in all the Reptilia it constitutes a highly important piece of the skeleton.

In Birds the *clavicles*, in consequence of the elasticity and strength indispensable in the composition of the bony framework of the shoulder in animals constructed for flight, present a very peculiar arrangement, being generally solidly anchylosed to each other in the mesial line, where they meet, forming a single bone, to which the name of *furculum* is generally given. In Birds, however, that are not organized for flight, such as the Ostrich, this peculiarity is dispensed with, and two distinct clavicles are found articulated with the sternum, as in the generality of Vertebrata.

In the Mammalia again the clavicles are much reduced in importance and frequently are entirely wanting, as in all the pachydermatous races. It is only when extensive movements are required in the anterior limbs, either for the purposes of flight, climbing, digging, or prehension, that clavicles are interposed between the shoulder of a quadruped and the anterior portion of the sternum, so as to form a kind of pivot on which the whole shoulder moves, and in the human subject the freedom of motion obtained for the arms and hands by this arrangement contrasts strongly with the fixed condition of the shoulder, both of Birds and Reptiles.

The *coracoid bone*, forming the third element employed in constructing the shoulder-joint of Vertebrate animals, is only fully developed in the Reptilia and in Birds. In Fishes it is but doubtfully represented by two bony pieces already referred to; but in all the Batrachian and Saurian Reptiles it constitutes the strongest support of the shoulder, abutting on the sternum on the one hand, and on the other firmly connected with the shoulder-joint. In the Chelonian Reptiles, too, the coracoids are very large, and remarkable on account of the extraordinary inversion of the skeleton of these animals, the scapulæ being here actually placed inside the thorax within the ribs, and fixed by ligaments to the sides of the bodies of the vertebræ; while the coracoid bones, equally placed within the thoracic box, are similarly circumstanced as regards the *plastron* or enlarged sternum that covers them inferiorly.

In Birds the *coracoid* bones are of peculiar strength and solidity, serving as buttresses to support the shoulder against the vigorous traction of the enormous pectoral muscles. It stretches from the anterior margin of the sternum, with which it is firmly articulated, to the junction of the *scapula and clavicle*, where it assists in forming the glenoid cavity.

Throughout all the Mammalia, with the exception of the Monotremata, the coracoid bones are wanting or only represented by a small apophysis, consolidated with the neck of the scapula, as is the case in the human skeleton, to which the term *coracoid process* has been generally applied.

The *humerus*, the first bone of the anterior extremity, is invariably a single bone interposed between the glenoid cavity and the forearm. It is invariably present throughout all the Reptilia, excepting of course the apodal Ophidian races, and is at once recognisable by the anatomist. In Birds, likewise, the *humerus* offers nothing remarkable except the mechanical arrangement of its articular extremities.

Neither in the Mammalia is there any aberration from the common type of structure, the only variations being in the length, form, or proportions of this piece of the skeleton, adapting it to the necessities of the different races of Mammifera.

The forearm, or second division of the upper extremity, is normally made up of two bones, called respectively the *ulna* and the *radius*. These are incomparably most complete in the human subject, where their admirable connections with the humerus, with each other, and with the hand, are amongst the most striking instances of perfect mechanism met with in the animal creation.

In Fishes and in the Batrachian Reptiles they are most imperfectly developed, and are invariably anchylosed together. In the Chelonian and Saurian Reptiles they become quite distinct from each other, but the movements of pronation and supination are extremely limited. The *ulna* of Birds is the principal bone of the forearm, while the *radius* is a separate bone easily distinguishable by the relations it bears to the other parts of the wing; here likewise, in consequence of the uses of the anterior extremity as instruments of flight, these bones are almost immoveably fixed in a state of pronation.

In the unguiculate Quadrupeds generally, the ulna and radius are separate bones, with a few exceptions, such as the *Cheiroptera*, where one bone only constitutes the forearm, but amongst the Ungulata they are frequently more or less consolidated and fused together towards their distal extremities, as, for example, in the Ruminants and in the Solidungula.

The *carpus*, forming the third division of the upper extremity, generally consists of several short and thick bones firmly bound together by ligaments, but allowing of sufficient motion between each other to afford a slightly moveable basis to support the parts composing the hand, either to prevent concussion in walking or to permit increased mobility to the fingers. When most completely developed, as they are found in the human subject, they are eight in number, to which names indicative of their shape have been applied, such as *scaphoides*, *lunare*, *cuneiforme*, *pisiforme*, *trapezium*, *trapezoides magnum*, and *unciforme*; but these names cannot be supposed to be applicable to the carpal bones of other Vertebrata, in which they present so many varieties both in their shape and position as frequently to be quite unrecognisable as the analogues of each other, their number too varying most considerably, either on account of the coalescence of elements originally distinct, or from their total suppression.

The bones of the carpus in Fishes are generally represented by four or five small pieces interposed between the bones of the forearm and the pectoral fin. With these bones the fin rays, however numerous, are connected; with the exception of the first, which articulates immediately with the radius. In some Fishes, as in the Lophius, these bones are extraordinarily lengthened, while the radius and ulna are diminished in proportionate size; so that some writers have mistaken the bones of the carpus for those of the forearm.

In the Batrachia, and in all four-footed Reptiles, they are small ossicles interposed between the bones of the forearm and metacarpal bones, resembling very much those of the human subject; but in Birds, in consequence of the peculiar condition of the hand, here converted into a wing, they are reduced to two, so disposed as to form with the bones of the forearm a mere hinge-joint moving laterally, so as to allow the wing to be folded up.

In the Cetacea the carpal bones exist, it is true, but so separated from each other by an interposed cartilaginous mass that they assist in forming a broad paddle, strengthened by superficial ligaments, and only useful for progression in the water.

In all other Mammalia the carpal bones are met with, their form and number varying with the uses for which the limb of which they form a part is adapted.

The *metacarpal bones* form the immediate basis on which the individual fingers are supported, and, accordingly, are as variable in their number and arrangement as are the digital portions of the anterior extremity.

In Fishes, owing to the numerous fingers or rays as they are here called, the metacarpal bones are met with in far greater numbers than in animals where the extremities assume a more concentrated form,—a fact most remarkably exemplified in the Chondropterygious Fishes, where the number of digital phalanges is enormous. But in Reptiles, where the hands are not only reduced to what may be called the normal type of structure, but developed in a medium condition, little remarkable is met with in this part of the hand. It is only as we come to animals appointed to extraordinary conditions of life that aberrations from the usual form become conspicuous, as, for example, in the feathered races. The metacarpus of Birds, although in some cases it might at first appear composed of a single bone, in others of two bones anchylosed together at both ends, contains, in reality, the elements of three metacarpal bones consolidated; two of these, which are much elongated, supporting the fingers, while the third, an exceedingly small element confused with the base of the central one, sustains the rudimentary thumb.

In the metacarpal bones of the unguiculate Quadrupeds there is nothing worthy of notice in this general survey of the osseous system; but in the Ungulata a coalescence almost as remarkable as in Birds is observable, whereby the peculiar structure of the feet of such animals is provided for. In the Ruminantia and Solidungula the whole metacarpal apparatus would at first sight appear to consist of a single bone, to which the name of canon-bone is generally appropriated; but this apparently single bone is easily seen to be in reality made up of two, anchylosed together throughout their whole length, so that the line of demarcation between them is only indicated by a deep longitudinal groove, visible on the anterior and posterior aspects of the bone; in most cases, however, there are two more lateral pieces, unattached to the principal or canon-bone except by the soft parts, but evidently real metacarpal elements in an imperfect and rudimentary condition.

The digital phalanges being the most remote from the central portion of the skeleton are likewise the most variable in number and appearance, being moulded into shapes as various as are the uses to which the anterior limbs are convertible, becoming in turn the framework of oars, of paddles, of pillars, of rakes, of wings, or of hands, in accordance with the different natures of the animals possessing them. Neither is it at all an easy task to say how many of these elements might exist in the construction of this part of the skeleton, seeing that the number of fingers that may enter into the composition of a hand seems not at all determinate, nor even the number of phalanges in a given finger. The pectoral fins of osseous Fishes, the representatives of the hands of higher Vertebrata, differ exceedingly in this respect, sometimes consisting of a single ray, at others being dilated and extended, as in the Flying Fishes, until both rays and phalanges become extremely numerous. The hand or pectoral fin of the Skates is perhaps one of the most remarkable structures that can be offered to the contemplation of the osteologist, whether we regard its apparently disproportionate size or the immense number of digital elements that enter into its composition; it forms, in fact, the great bulk of their bodies, and is made up of upwards of a hundred distinct fingers, each composed of numerous phalanges of enormous length. Throughout the Serpent tribes all traces of anterior extremities are lost, but in the Anourous Batrachia fingers again appear under a new and more elevated form, although feeble when compared to the digital phalanges of the hinder extremities in the same Reptiles.

Throughout the Saurian and Chelonian races as they now exist, nothing remarkable appears in the construction of this portion of the skeleton, the chief modifications observable being in the number, length, and position of the fingers, although in extinct forms of nearly allied genera, such as the Ichthyosaurus and Plesiosaurus, the number both of toes and phalanges are so prodigiously increased that we are once more reminded of the fins of Fishes.

The digital phalanges in the wing of a bird are reduced to an exceedingly rudimentary condition, the thumb being represented by a single bone. The central or radial finger is the longest and most complete, consisting, when fully developed, of three distinct joints, though sometimes there are only two. The ulnar or third finger is, like the thumb, represented by a single phalanx appended to the distal extremity of the ulnar metacarpal bone.

In all the mammiferous Quadrupeds possessed of unguiculate feet, the digital phalanges of the anterior extremity present nothing worthy of special notice in this place, minor differences being noticed under the proper heads; but in the ungulate Pachydermata, such as the Ruminants and Solipeds, remarkable exceptions to the usual arrangement are met with. In the Ruminants only the two central fingers are well developed, each consisting of three large phalanges, the distal one of which is enclosed in a strong hoof, so as to give the cloven appearance to the whole foot which is so characteristic of the order; but besides these, two rudimentary toes exist, one on the outer, the other on the inner side of the foot, but so small as not to reach the ground or to be serviceable in the ordinary progression of these creatures.

In the Solipeds even the division between the central large toes that exists in the Ruminant becomes obliterated, and the whole foot appears to be made up of a single toe consisting of three strong phalanges, the distal one being encased in a large semicircular hoof. Even in these animals, however, rudiments of two other toes are distinguishable, but very imperfectly developed.

Ilium.—This is the principal bone entering into the composition of the pelvic arch, and frequently is the only one met with in this part of the skeleton. In the osseous Fishes it is not yet connected with the spine, so that the posterior part of the body is left perfectly free and untrammelled, in order to allow of the extensive movements of the tail required for the propulsion of these aquatic animals through the water. There is consequently here no sacrum, and we are not surprised to see the posterior limbs extremely variable in their arrangement, being placed far back or advanced towards the anterior part of the body as circumstances require. Even in the cartilaginous Fishes the pelvis has no connection with the spine, the whole consisting of a broad transverse osseous band placed beneath the terminal portion of the abdomen.

In the Batrachia, too, the iliac bones retain to some extent the form of ribs, and in the Frog are two bones of considerable length attached to the prolonged transverse processes of the last vertebra, which of course, in this case, represents the sacrum.

In the Toad another step is made towards strengthening the posterior part of the spine, preparing it to support locomotive organs of greater energy by fixing the iliac bones to two of the vertebral transverse processes, forming a sacrum composed of two bones, which is in fact the usual condition of this part of the skeleton in the higher Reptiles.

In the Chelonians, however, the iliac bones are again attached to a single vertebra and pelvis, like the bones of the shoulder placed internal to the ribs which form the carapax or dorsal shield.

The *ilium*, in all the class of Birds, is enormously developed in proportion to the unfavourable circumstances under which they support themselves upon their posterior extremities. It extends along the sides of the vertebral column, to which it is solidly anchylosed, converting into one immense sacrum from eight to nineteen of the posterior vertebræ, which are so completely fused to each other and to the iliac bones that their number is only distinguishable from the positions of the intervertebral foramina through which the nerves escape from the spinal canal in this region.

In Mammals the iliac bones are likewise greatly developed, except in the Cetacea, where, in consequence of the necessity for fish-like flexibility in the hinder part of the body, no hinder extremities exist. The sacrum is composed of a considerable number of vertebræ here anchylosed together and considerably modified in their form, to which the broad *ossa ilii* are firmly secured by ligaments and an interposed cartilage, giving a firmness to this part of the skeleton second only to what is observable in the feathered races.

The *ossa ischii*, the second elements entering into the composition of the pelvic framework, are not so invariably present as the iliac bones. In Fishes they are not to be found: but in all the Reptilia, where the elements of the skeleton remain permanently disunited to a much greater extent than in warm-blooded animals, they are constantly present, except, of course, where the hinder extremities are deficient, and are separated by a very distinct line of demarcation from the other bones of the pelvis.

As in the shoulder, the articular cavity for the attachment of the anterior limbs when all the elements of that part are fully developed, is formed by the union of three bones, so likewise in the pelvis, which is only a repetition of the same apparatus modified in form, do all the three bones of which it consists enter into the formation of the cotyloid cavity, a circumstance which, in Reptiles, is particularly conspicuous.

In the class Aves, notwithstanding the aberrant condition of the pelvis, the *ischia* are easily distinguishable from their position, bounding as they do the obturator foramen on the one side, and the sacro-ischiatic notch on the other.

In the Cetacean Mammals this element of the skeleton is again obliterated, but in all the other orders it is present, and in the earlier stages of life is readily demonstrable as a distinct bone of the pelvis.

The *ossa pubis* are the third pair of elements entering into the composition of the pelvic cavity, and to these the same remarks are applicable as we have already made concerning the ischia. In Fishes they are not present, but throughout the Reptile orders that possess a pelvis they are very distinct and important parts of the skeleton, meeting each other anteriorly in the mesial line, where they are united by a strong symphysis.

The pubic bones in Birds occupy a corresponding position; they are here, however, remarkable from the circumstance that their distal extremities never (except in the Ostrich) meet to form a pubic symphysis, but are always widely separated from each other, an arrangement which is here convenient to permit of the extrusion of the egg through the pelvic cavity, and may be permitted in this race of animals in consequence of the prodigious consolidation of the dorsal parts of the pelvis.

In the Cetacea only the pubic elements of the pelvis are developed, both ilia and ischia being deficient, so that they are quite detached from the rest of the skeleton. In all other Mammalia they correspond both in position and general arrangement with what is found in the human subject.

The *marsupial bones* are peculiar to the marsupial division of Mammals. They are two triangular pieces articulated to the anterior surface of the pubic bones, and imbedded in the parietes of the abdomen behind the marsupial pouch, which they assist in supporting. It has been asserted that rudiments of these bones may be traced even in the human subject in the shape of minute cornicles sometimes attached to the pubis.

The *femur* represents, in the posterior extremity, the humerus of the anterior, articulating immediately with the pelvic arch, but modified in form according to the difference of its function. In Fishes this element of the skeleton does not exist at all, the digital rays and tarsal bones of the ventral fin, the representative of the posterior extremities of other Vertebrata, being affixed immediately to the pelvic bone, which sustains it. In the Perennibranchiate Amphibia it is but very feebly developed when the hinder extremities are present, which is not always the case. In the Anourous Amphibia, however, as, for example, in the *Frog*, it suddenly assumes a very great importance in accordance with the saltatory habits of those Batrachia. It exists also in all other quadrupedal forms of the Reptilia, only modified in shape according to their different modes of life.

In Birds the femur is short and strong, but presents no peculiarity requiring special notice.

In the Mammalia, likewise, except in the Cetacea, it is invariably present, its size and shape altering in the different tribes as their habits vary.

The *tibia*, the principal bone of the leg in all quadrupedal Vertebrata, does not exist in Fishes, where all the elements of the skeleton, usually interposed between the foot and the pelvis, are found to be deficient.

In the Batrachian, Saurian, and Chelonian Reptiles it is invariably a bone of very considerable importance, whether it be united with the other bone of the leg, the fibula, or remain separate and distinct.

In the feathered races this bone is of great strength, having to support the weight of the body in a very unfavourable position, and in all the Mammalia that are possessed of posterior extremities it is necessarily present.

The *fibula*, which in the hinder extremity represents the ulna of the anterior limb, like that bone, is not unfrequently very imperfectly developed, especially where great strength is required in this part of the limb, and mobility becomes a secondary object. In Fishes it is not yet developed. In the Batrachian Reptiles it exists, but is generally so completely anchylosed to the tibia throughout its whole extent as only to be distinguished from that bone by very accurate examination. In the Saurian Reptiles it is a distinct and very important bone, as is likewise the case in the Chelonians, although here the two bones of the leg are so firmly connected by ligaments that but little motion is permitted.

The fibula of Birds is a mere rudiment, a slender splint appended to the external aspect of the tibia, distinct above, but inferiorly completely lost, being gradually solidly united to the latter bone, with which it becomes completely confused.

In the Monotremata, notwithstanding the near relations that exist between these singular quadrupeds and the feathered races, the fibulæ are very largely developed, as likewise in most of the unguiculate Quadrupeds; but in the ungulate Mammalia the fibula is reduced to a mere rudiment attached to the outer side of the tibia.

The *tarsal bones* are, in the posterior extremity, the representatives of the carpus of the anterior, but from various circumstances are very considerably altered in form, and not unfrequently differ in number from the latter, even in the same animal, in consequence of the very different offices not unfrequently assigned to the two pairs of limbs. In Fishes they are very imperfectly developed, or confused with the other elements entering into the composition of the ventral fin. In Frogs and Toads, however, they are very distinctly formed, being in these amphibious reptiles six in number; but of these the two proximal ones, corresponding to the *astragalus* and *os calcis*, are remarkably elongated, and by the uninformed might easily be mistaken for the tibia and fibula. In Saurian and Chelonian Reptiles they present what may be called their normal or medium state of developement, the os calcis being here left prominent for the insertion of the extensor muscles of the foot.

No tarsal bones are distinguishable in the adult bird, the few elements which in the young animal are developed by distinct points of ossification being rapidly confused with the metatarsal portion of the limb, so that both these divisions of the hinder extremity are here represented by a single piece, to which the appropriate name of tarso-metatarsal bone has consequently been applied.

In all unguiculate Mammalia the tarsal bones are well developed and more or less resemble the human; but in the Ungulata, owing to the extreme length of the *metatarsus* or canon bone, they seem to occupy a position corresponding with that of the knee in other animals; and the remarkably prominent *os calcis*, to which the *tendo Achillis* is fixed, is well calculated to remind the anatomist of the olecranon of the ulna.

The metatarsal bones are but a repetition of the metacarpal bones of the atlantal extremity, and immediately support the digital phalanges of the foot, varying in number as the toes are more or less numerous. In their most normal state of developement these bones are five in number as in the human skeleton, but from this variations occur in almost every order of Vertebrata.

The metatarsus of Reptiles is, however, well developed, consisting of a series of moderately elongated bones extended between the carpus and the proximal phalanx of the corresponding toe, but offering nothing worthy of special comment.

The tarso-metatarsal bone of Birds, representing both the tarsal and metatarsal portions of the skeleton, seems to consist of three and sometimes four metatarsal bones consolidated into one piece. These are distinguishable inferiorly by the four trochlear surfaces that support the moveable toes; while the presence of an ossified spur in some gallinaceous birds, regarded by many anatomists as the rudiment of a fifth toe, might indicate the existence of a fifth metatarsal element lost in the general consolidation of these pieces.

In all the unguiculate Mammals the metatarsal bones hold the same relations with the other bones of the foot as in the skeleton of Man, and need no special notice; but in the Ungulate families their appearance and arrangement are necessarily much changed. In the Solipeds and Ruminants the metatarsal division of the extremity is so much elongated as to constitute a very considerable portion of the limb. It is principally made up of a single piece generally called the "canon bone," which in reality consists of two enormous metatarsal bones consolidated into one, being fused together in the central line along their whole length, although the real composition of the canon bone is always distinguishable both on account of a deep furrow which indicates the union of the two pieces, and from the condition of the two widely separated trochlear surfaces at its distal extremity. Besides the two largely developed pieces forming the canon bone, two other metatarsal pieces assist in forming the foot of a Ruminating Quadruped; these sustain the supplementary toes developed in a rudimental condition on the outer and inner aspects of the member.

The *digital phalanges* of the posterior extremity are among the most variable elements of the skeleton, being, like those of the anterior, made subservient to a great variety of uses both in terrestrial and aquatic forms of Vertebrata.

In the osseous Fishes they are represented by the fine rays of the ventral fin, and are of course employed in natation; but in the cartilaginous Fishes, as the Sharks and Rays, although the resemblance between this part of the skeleton and the feet of higher animals is more striking than in the osseous races, they are appropriated to a different office, serving the purpose of claspers, whereby the intercourse between the sexes is facilitated.

Throughout all the Reptilia that possess hind feet, the phalanges of the toes offer nothing remarkable; neither in Birds is there anything peculiar in their structure, the only circumstances of interest connected with this part of the skeleton in the feathered races relating to the number and disposition of the toes, and the presence of more or less numerous joints entering into their composition.

In the Mammalia this part of the foot corresponds in its composition with that of the hand, and therefore need not be further noticed.

In enumerating the elements of the endoskeleton it would be improper to omit certain supplementary pieces, which, though not strictly belonging to the osseous system, are of important mechanical assistance to the muscles inserted into different portions of the skeleton. These are developed in the substance of various tendons where much friction is encountered, or where it is of importance to remove the line of traction to some distance from the centre of motion in order to gain additional leverage. When developed in the tendons of the fingers or toes, these detached pieces of osseous substance are called "sesamoid bones," but in such situations their existence is by no means constant. Connected with the great joints corresponding with the knee and elbow of the human subject, bones of this kind are very generally developed, and their size and importance renders them worthy of special remark. In the anterior extremity the superadded bones are named "olecranon," and very generally are found solidly cemented to the proximal end of the ulna, forming a prominent process, that gives great mechanical advantage to the extensor muscles of the forearm. The corresponding bone appended to the knee-joint has, from its condition in the human subject, received the name of "patella."

Such being the elements employed by nature in constructing the locomotive extremities of Vertebrate animals, our only wonder is that by simply modifying the figures of the bones, by suppressing some and exaggerating others, or else by fusing several of them together, such infinite diversity of apparatus is provided in the various classes of Vertebrata. Seldom, indeed, does a limb present all the pieces we have enumerated in a complete state of developement, and frequently the majority of them, or even the whole series, is entirely dispensed with. In many Fishes, as in the Lamprey and Myxine, all four extremities are absolutely wanting, a circumstance which again becomes remarkable in the case of Ophidian Reptiles. Occasionally the hinder only are called into existence, and that in a very rudimentary state, as for example, in some Serpents, Anguis, Boa, &c. More frequently the anterior limbs are found without the posterior; such is the case in the apodal Fishes, in the Siren and Bimanes among Reptiles, and still more conspicuously in the Cetacea.

Exoskeleton.—Having thus examined all the elements that belong properly to the osseous system or *endo-skeleton*, we must now turn our attention to another important system of organs equally concerned in building up the framework of the body, and that to an extent which the human osteologist would scarcely imagine possible. We allude to the external or cuticular skeleton, which, although reduced in Man to a most rudimentary condition, being represented merely by the common cuticular covering of the body and its appendages, the hair and the nails, we shall find among the lower Vertebrata performing a much more important part in the animal economy, and occasionally entering largely into the construction of the organs of locomotion, replacing and not unfrequently actually assuming the appearance and office of the *endo-skeleton* or proper osseous system. Examined in their remotest aspects, few textures indeed appear less allied, the osseous tissue and that of hairs, horns, feathers, and other cutaneous appendages; nevertheless we doubt not that, on taking an enlarged view of the subject, it will not be difficult to prove that the two are absolutely interconvertible, both in use and even composition, the cuticular skeleton being not unfrequently had recourse to by nature to eke out and complete organs for the construction of which the elements of the endo-skeleton would have been insufficient.

Let any one who is only conversant with the composition of the skeleton of Man, or of the higher Vertebrata, examine that of a fish, more especially of one of the osseous Fishes, and he will soon perceive how impossible it is to point out anything analogous to a very considerable number of the parts composing it, in the bony framework even of those Reptiles that are most nearly approximated to Fishes in their general economy, or from the elements above enumerated, various as they are, to build up those additional structures that render the osseous support of a fish's body so complicated and so aberrant in its composition from what is seen in any other class of Vertebrate animals. In the first place there are numerous bones forming a chain of osseous plates surrounding the inferior margin of the orbital cavity, which have been named by Cuvier "*suborbital bones*," and by Geoffroy "jugal bones," although, having already seen that the jugal are represented elsewhere by an important element easily idenfied, it is surely anomalous, to say the least of it, to find the same element thus multiplied and divided, more especially when in many of the hard-cheeked fishes, such as the Gurnard, these supplementary pieces become the largest bones of the face.

The *opercular bones*, which form the gill flaps of the fish, are a set of bones which from their very office are evidently peculiar to the skeleton of a fish, and could scarcely have been suspected to have any analogue in animals totally destitute of gill openings, as are all other Vertebrata in their adult condition. These bones are four in number, and have received from writers on ichthyology the following names: 1st, the *preoperculum*,* (*fig.* 436, 30) which forms the basis supporting the other three; 2nd, the *operculum* † proper, (*fig.* 436, 28) articulated to the former, on which it moves like a door on its hinge. Beneath the last-mentioned bone is a third, named the *suboperculum*,* (*fig.* 436, 32) and still lower down placed immediately behind the articulation of the lower jaw, a fourth, to which the name of *interoperculum* † (*fig.* 436, 33) has been applied.

In the Chondropterygii this apparatus is entirely wanting. To explain the analogies of these pieces the most desperate theories have been broached by transcendental osteologists, the boldest and most celebrated of which is that of Geoffroy St. Hilaire, that these opercular bones are the *ossicula auditûs* reproduced in an altered form after they were no longer required to form part of the auditory organ; an opinion which has found supporters even in this country notwithstanding the withering criticism of Cuvier, who, remarking upon this theory, very justly observes, that he has seen but little of such sudden reappearances of parts after they had been progressively made to disappear in the scale of animal life. Cuvier was compelled to regard the opercular bones as being superadded elements of the skeleton peculiar to Fishes, and having no representatives in other Vertebrata. De Blainville suggested that the pieces in question might be derived from a dismemberment of the lower jaw, by the detachment of the opercular elements from the ramus; but this hypothesis is refuted by the fact that in some Fishes, as the *Lepidosterus*, all the elements of the inferior maxilla are co-existent with the opercular apparatus. Professor Owen first suggested that they were mere derivations from the dermal skeleton, an opinion that seems every day to receive confirmation.

The *supra-temporal* bones of Fishes, a chain nearly resembling the *sub-orbital*, which in many species arches over the temporal fossa, belong to the same category, and cannot be said to resemble any bones found in other creatures.

But the most anomalous of all the bones found in a fish's skeleton are those large and important ones that support the azygos fins placed along the mesian line of the body, constituting the dorsal, caudal, and anal fins. These bones consist of several distinct pieces, and frequently assume a very complex structure: first, there is the fin ray itself, either simple, as in the dorsal fins of the Acanthopterygii, or many-jointed, as in the fin rays of Malacopterygious fishes. These moreover are individually articulated with other pieces of a more decidedly osseous character, called the interspinous bones, which are imbedded in the flesh of the back, and might be, as indeed they have been, mistaken for appendages to the neuro-spines of the vertebræ.

The hypothesis promulgated by Professor Grant upon this subject is as follows: "The spinous processes in Fishes give rise to other pieces. The spinous processes extending from the vertebræ of the fish when they have become largely developed themselves, give origin to new bones and afford us an illustration of a

* *Tympanal bone* (Geoffroy). *Malleus* (Spix).
† *Stapeal* (Geoffroy). *Incus* (Spix).

* *Malleal* (Geoffroy).
† *Inceal* (Geoffroy). *Stapes* (Spix).

fact which is remarkable for its uniformity in other parts of the skeleton and in other animals. A separate centre of ossification is developed, a new source of nutrition is conveyed directly to the extremity of the part—a new bone is formed from the end of the spinous process." But even this dilatable explanation is by no means sufficient for the required purpose, for having developed in this way the interspinous bones from the spinal elements of the vertebræ, the fin rays themselves are referred to the same source, and thus materials are afforded for complicating the endoskeleton *ad libitum*, upon the simple supposition that when any element becomes inordinately developed, it can develope other elements to eke it out.

Geoffroy adopted another mode of explaining the origin of the supernumerary bones that support the dorsal and anal fins of fishes. Supposing the upper and lower vertebral spines (i. e. the neuro-spines and hæmo spines) to be each composed of two elements conjoined in the mesial line, he asserts that, instead of remaining side by side, one half of the spine is removed and placed above the other to form the interspinous bone. Yet even this would by no means get over half the difficulty, for the fin rays themselves remain to be accounted for, and where are elements to be procured for the construction of these? Moreover, as Cuvier remarks, it by no means unfrequently happens that several interspinous bones belong to a single vertebral spine, a circumstance which is quite incompatible with the supposition that any dismemberment of the spine can account for their presence.

Failing, therefore, to find any materials for the construction of the bones we have enumerated among any known elements of the endoskeleton, we are compelled to look elsewhere, and shall soon find, by tracing the exoskeleton of Fishes through the different aspects under which it offers itself, abundant means of supplying all deficiencies.

The scales that usually invest the bodies of ordinary Fishes would certainly appear at first sight to have no relationship whatever with the osseous system, as neither in texture nor mode of growth do they at all resemble bone, being simply composed of layers of epidermis secreted one after the other until they attain the required thickness. But these epidermic scales, if but very slightly exaggerated, become susceptible of such varieties of form and structure that they often entirely lose their nature, and becoming solidified until they emulate true bone in hardness and compactness of structure, are often converted into weapons of defence or attack of very diversified descriptions; the dense and bone-like armour of the *Ostracious*, the formidable spines of the *Diodon*, and even the crystalline tooth-like points that stud the skins of *Sharks* and *Rays*, forming what is called *shagreen*, being mere modifications of the same cuticular appendages. Having advanced thus far in tracing the changeable character of the scale of a fish, adapting it to various functions, we are quite prepared to admit other important facts of still greater interest. It is only necessary to examine the spines met with upon the back of a common *Skate* or *Thornback* to perceive that they are of very different character in different parts of the surface of the body. The minute scale-like points are at times converted into large hooks fixed upon the surface of the skin, which really become formidable defences. On approaching the mouth they become again so much reduced in size as to represent an exceedingly fine tessellated pavement, which covers the lips and passes even into the interior of the mouth. On reaching the margins of the upper and lower jaw their appearance again becomes changed; they are increased in size and hardness, being in fact converted into teeth which pave the whole surface of the jaw, covering it with osseous plates, or powerful hooks, or cutting teeth, such as the Shark possesses; but these teeth are still quite unconnected with the jaw and may be easily stripped off with the cuticle, of which, indeed, they form a part. Even the tongue itself is covered with similar plates of hard substance, smaller in size indeed, but in every thing comparable to the teeth both in character and mode of growth. Finding that the teeth in their simplest form are merely epidermic structures, nothing would be more easy than to point out a long series of almost insensible gradations through which they become more and more decidedly connected with the bones of the endoskeleton, until at length they absolutely become implanted into it, and fixed to the jaw-bones as intimately as if they were really themselves portions of the true osseous skeleton. The ligamentous bonds of union between the teeth and jaw-bones of *Lophius*, the soldering together of the teeth, and the numerous bones which, in Fishes, are made to support dental appendages, and the gradual appearance of alveolar depressions in the jaws of the higher Reptilia, are all so many steps of progressive approximation, the intermediate phases of which the scientific reader will easily supply. These facts therefore satisfactorily prove that, as far as the teeth are concerned at least, the exoskeleton and endoskeleton are so nearly approximated in texture that they actually become appendages one of the other, as the teeth are infixed into the jaw-bones that support them.

Having thus convinced ourselves that in the case of the teeth the cuticular and osseous systems become articulated together, or so consolidated as only to be distinguishable from the microscopic texture that they respectively present, we are prepared with greater confidence to expect similar phenomena in other parts of the body, and to find the exoskeleton and endoskeleton to a certain extent vicarious in function and interchangeable with each other.

No one will deny that the spines of the common Sticklebacks (*Gasterosteus*), or the bony-looking weapons affixed to the root of the tail of the *Sting-ray*, are cuticular in their nature and mere derivations from the exoskeleton; yet we have only to advance one step further, and we find spines in every way similar in their nature absolutely articulated by curious and most beautiful moveable joints to different parts of the osseous system, of which we need only adduce as instances the fishing filaments upon the back of the head of *Lophius*, and the powerful weapons of *Silurus* and *Balistes* elsewhere described (vide Art. PISCES), where muscles are implanted into the spear-like arms here formed entirely from the cuticle, although brought into close union with the bones of the real skeleton.

Having arrived thus far and found in the cases alluded to that epidermic spines, when thus far exaggerated in their dimensions, are really converted into fin-rays and moved by appropriate muscles, it is impossible to deny that such organs may have a similar origin in other parts of the skeleton, and that the rays of the azygos, dorsal, caudal, and anal fins, as well as the interspinous bones, which cannot be referred to any known element of the endoskeleton, are in reality derivations from the exoskeleton, although implanted in the flesh and wielded by an appropriate system of cutaneous muscles. Even in their internal texture these pieces become assimilated to real bones, and that to such an extent that it even yet remains for the minute anatomist and the microscopical observer to point out satisfactory differences between the two skeletons when they thus become blended together, notwithstanding the wide interval which separates the scale, the hair, or the feather, all modifications of the epidermic system, from the tooth in its fully developed state, or from perfectly organized bone permeated by vessels and nourished by interstitial deposition.

OSSEOUS TISSUE. BONE. BONE SUBSTANCE.—The tissue of bone has, within the last few years, undergone close examination by various anatomists of note. These examinations have been followed with much success, and have led to much increase of knowledge of the nature of bone, both as regards its developement and its minute structure.

The general character, the varieties of external conformation, and the anatomical relation of bone to the contiguous textures, have been ably related in a previous article. Under the present head it is proposed to treat only of the minute structure and of the developement of bone.

For the sake of precision in the description, the elements which conjointly form bone, or which are commonly found connected with osseous formation, will be considered under separate heads.

But before proceeding to this consideration of the separate parts it will be well to give a general description of them collectively in their natural relations.

The canals which are found every where traversing variously the substance of bone, and giving passage to the bloodvessels for the nourishment of the tissue, are known by the name of *Haversian canals*, Clopton Havers having been the first to give a full description of them. The parietes of these canals have a laminate arrangement. The laminæ themselves are numerous and placed concentrically, the internal lamina, that which is in immediate contact with the vessel or vessels, being the most distinctly marked, and each succeeding one, as you proceed from the canal, having a less distinct outline.

Besides the concentric laminæ there are others which surround the exterior of the bone, and may be known as the superficial laminæ. In connection with the latter as well as the former system of laminæ are a third set, which cannot be traced to belong to either of the foregoing orders, but which are placed between them, and form the bond of union between each system.

Late writers on this subject have said much of the corpuscles of bone; these are small cells of oval form placed between the laminæ, and having numerous distinct tubes running from them in almost every direction. They have not inaptly been compared to a spider with many legs.

The corpuscles, or, as others have called them, the calcigerous cells, have a definite relation to the Haversian canals and to each other. These points, however, will be considered in detail in a subsequent page.

The foregoing are the leading points that are spoken of in treating of the structure of bone, namely, *the Haversian canals, the osseous laminæ*, and *the corpuscles*. But, upon a closer view, it will be seen that the laminæ only are bone; the canals and corpuscles are spaces existing in bone, and are not really necessary to the existence of osseous tissue, though they are necessary to its existence where the amount of substance is appreciable to the unaided senses.

Having given a general sketch of the structure as it appears when placed under a low magnifying power, it will be well to describe particularly each of the points which have been noticed.

The most important and that which will be placed first in the division is the bone substance of which the laminæ are composed.

Of the substance of bone, or hyalitic substance.—Writers have, with one or two exceptions, considered the substance of bone as homogeneous and without appreciable structure. If, however, it be examined under advantageous circumstances, with high magnifying powers, there will be no difficulty in detecting a very definite though delicate structure. For the purpose of examination it is best to take a very small portion of a thin plate of bone; such may be found in the œthmoid bone of small animals, as of the rat. If the piece be well se-

Transverse section from the dense portion of the femur.

a, Haversian canal; *b*, concentric laminæ; *c*, laminæ of connection; *d*, corpuscles, with their system of tubes.

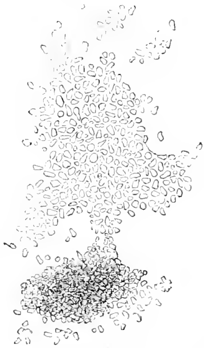
The parts marked *a*, *b*, and *d* constitute an Haversian system. The figure includes three systems with laminæ of connection uniting them.

lected, it will be found to contain no Haversian canals or corpuscles, but to be extremely thin and transparent. Such a portion, when viewed with the one-eighth of an inch object-glass of Mr. Powell's microscope, will present a delicate granular aspect with the surface nodulated. This granular appearance arises from the substance of the bone being composed of minute irregularly spherical granules. It is not difficult to trace this structure in any specimen of bone, though in some it is much more distinct than in others. Specimens put up in Canada balsam do not show the minute structure very well. It is best to place the object between two slips of glass with a little plain water.

A delicate spicula from the point where ossification is going on is usually very good for illustrating the granular tissue.

But the granules may be obtained separated from each other, so that each individual may be examined apart from its fellows. When so exposed to view, they exhibit a tolerably regular character, being mostly spherical, some few having an oval form. In some specimens the oval predominates over the spherical conformations. Often a few will be found which are egg-shaped, with the smaller end elongated, (see *fig.* 449,) though to no great extent. The osseous granules may be gained by subjecting bone to high-pressure steam, or to a red heat, till all the animal matter is removed. In either instance the granules may be obtained by taking

Fig. 449.



Ultimate osseous granules obtained by depriving the bone of its animal matter.

a small portion of the so treated bone, saturating it with water, and then gently reducing it to a powder between the slips of glass. By this manipulation the granules individually will be rendered evident when the specimen is examined under a high power. But, by the breaking down of the mass, many granules are necessarily broken; to remedy this imperfect and confused state of the specimen, a little dilute muriatic acid should be placed upon the glass in contact with the specimen. Solution of the powdered mass will instantly commence, but the broken granules will have disappeared before the entire ones are appreciably affected. If at this point of the experiment the acid be removed and replaced by pure water, a perfect specimen will be gained. In examining the tissue under consideration it is most satisfactory to watch the action of the acid upon the calcined or steamed bone, and especially its action upon the small masses, for in these, when undergoing the action of dilute acid, the granules composing them become particularly distinct, so that their individual character may be studied; and if the solvent be not removed, their separate disappearance may be watched as the superficial ones are exposed and acted upon by the solvent fluid. If the acid be left with the so treated bone for a sufficient length of time, all the earthy matter will be dissolved and there will remain a transparent indistinctly cellular mass, which may be supposed to be an intergranular substance, the purpose of which was to unite the granules into a compact whole.

Bone which has been treated with dilute acid without the previous removal of the animal matter, soon loses the earthy component, leaving only the animal. This, however, does not tend to develope the granularity; indeed it seems, in most cases, to render it less distinct than in either the unaltered or the calcined bone. The granules themselves are subject to some variety in size, commonly varying from the one-sixth to one-third the size of a human blood globule.

Of the laminæ.—The form taken by the bone substance is that of laminæ, and these laminæ have a definite arrangement, so much so that three distinct systems may be recognised, namely, laminæ of the Haversian canals; secondly, the laminæ which connect the Haversian systems; and thirdly, the laminæ which form the surface of the bone and enclose the two previous orders.

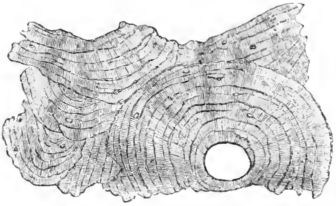
The laminæ of the Haversian canals have a concentric arrangement, and present, when divided transversely, a series of more or less distinct and perfect rings: see *figs.* 448 and 450. They are subject to considerable variety in number, but the more common amount is ten or twelve. Of these, the internal lamina, that which forms the parietes of the Haversian canal, is most distinctly marked, while each succeeding one as you proceed outwards becomes less distinct. The concentric laminæ with bone cells and central canal have received the name of Haversian system from Dr. Todd and Mr. Bowman in their work on Physiology.

Connecting these Haversian systems is a second series of laminæ, without which the former would exist but as a bundle of loose tubes. (See *fig.* 448, *c*).

In this substance we find the laminated arrangement less distinct, far less regular, and the laminæ individually subject to great irregularity of thickness. It is often also more transparent than either the Haversian or external system. Bone cells contained in it are also more irregular in shape than those found in other situations. The last division consists of those laminæ which surround the exterior of the bone. These have greater individual extent, but are the least numerous. They are continuous with the laminæ of the Haversian system whenever the latter arrive at the surface of the bone; the external laminæ in this case being continuous with the inner laminæ of the Haversian system.

Some authors have doubted the existence of a laminated arrangement in bone. If, however, young bone be examined, all doubt upon the subject will be dispelled, and especially if it be first macerated in weak muriatic acid, when the appearance represented in *fig.* 450 will be seen. In bone so treated the laminæ may with

Fig. 450.



The laminæ as they appear after the removal of the animal matter by the action of acid.

the assistance of two needles be separated. In the bones of old animals the laminæ are much less distinct; in these, however, they may be demonstrated if acid be used. Though the external lamina is very distinct, and therefore the boundary of each Haversian system, yet in bone of advanced age the distinctness is lost in common with the definite outlines of the three orders of laminæ. The cancelli of the cancellous portion of bones are but enlarged Haversian canals, which in addition to vessels contain fat; the laminæ therefore which form the walls are those of the Haversian system.

In connection with this division of the subject, the effect of madder given to an animal with its food upon the osseous system may be noticed, since the colour is imparted to the laminæ. By the taking of madder into the stomach the effect of giving a deep red tinge is very soon observable. In a pigeon the bones were rendered brilliantly red in twenty-four hours. In a young pig a similar effect was produced in three weeks.

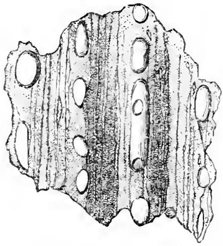
On making sections of bone so affected the colour is found to be present in the external laminæ of the bone, and in the inner laminæ of the Haversian system, thereby proving that the action of colouring takes place upon those surfaces which lie in contact with vessels. This fact, with many others in this article, was mentioned in a paper by the author read before the Royal Society in June of 1838.

Of the Haversian canals.—These canals

have to be considered in relation to their number, their size, and the parts which they contain. The number of canals in a given space is perhaps a little variable, but this variation will be regulated in some degree by the situation of the bone, but more especially by the age of the bone. Thus the transverse section of the femur of a human fœtus of seven months will present many more canals than a section of equal measurement from the femur of an adult.

In certain fish of which the Scarus is a specimen, the Haversian canals are extremely numerous, so that bone cells become unnecessary, for here we find very few indeed, and in some sections none. (*Fig.* 451.)

Fig. 451.



Section of bone from the Scarus, showing that where the Haversian canals are very numerous the bone cells are absent.

The size of the Haversian canals takes a considerable range, varying from the $\frac{1}{303}$rd to the $\frac{1}{500}$th of an inch, as stated by Mr. Smee. In the young subject they seem larger than in the old. But by far the most marked difference in size of these canals is to be observed in the antlers of the stag at different periods of their growth. At an early period of the existence of the antler, the vascular canals are large and numerous, while at the time of their completion in size the canals are less numerous in an equal space, and very small: indeed many seem all but obliterated. The density of bone is produced more by the small size of the canals than by their comparative infrequency, though undoubtedly they are less frequent in the compact bone, as that composing the shafts of long bones.

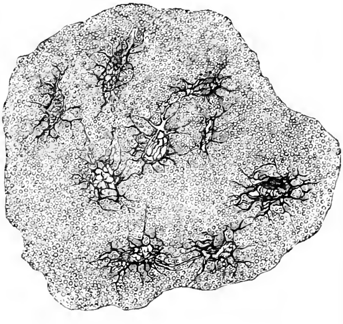
In tracing individual canals, it will be found that the majority maintain the same size as far as we can follow them. This is not, however, observable in all. If a large canal be taken where it first enters the substance of the bone, it may be found giving off branches from time to time in various directions, and then again sending off smaller branches, which anastomose freely with each other, often joining at right angles.

Although it is very easy to trace a large canal pervading a bone, and then dividing from time to time into smaller ones, I have never been able to satisfy myself that these small canals again unite to form a second large canal, and thus to leave the bone. I am therefore led to the opinion that such does not occur, but that the small even-sized canals open and give exit to their vessels upon the surface of the bone generally, while the large canals give entrance to arteries.

The Haversian canals undoubtedly give passage to bloodvessels, which is their principal, if not their only purpose. Whether they contain one or more vessels seems to admit of a little doubt. Dr. Carpenter, in his work on Physiology, states that they contain an artery and vein. From my own observation I am not able to confirm his view. Indeed I am disposed to the opinion that they give passage to one vessel only; that the larger canals which are found entering the bone convey an artery; that it divides from time to time after the manner of the canals described; and that the vessels emerge again from the surface of the bone as capillaries. This branch of the subject requires some further investigation. The foregoing observations apply only to dense bone. Where bone is cancellated for the reception of fat, the vessels occupy but a small space in the cancelli.

Of the corpuscles or cells of bone; also called *lacunæ* by Dr. Todd and Mr. Bowman.— The so-called corpuscles are nothing more than small cells existing in the substance of the tissue, and might with propriety be called *bone cells.* Some anatomists have designated them

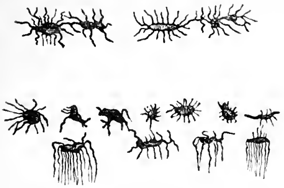
Fig. 452.



Section of a flat bone, showing the bone cells in the granular tissue.

calcigerous cells, from the supposition that they contain in their interior an amorphous salt of lime. That this view is incorrect will be subsequently shown. The cells cannot be described as having any definite unvarying shape or size. The general form is a compressed oval, though not unfrequently they are circular, but flattened from side to side. Again, they are sometimes almost triangular in their outline, while in other instances they approach a linear shape. These are the most common varieties of outline to which the bone cells are subject; as they occur in the bones of man and the higher animals. But connected with the cells are numerous delicate branching tubes, which are slightly dilated as they enter the cells. The number arising from each cell does not allow

Fig. 453.



The forms assumed by the bone cells in man.

Fig. 454.

Various forms of bone cells found in the bone of the Boa Constrictor.

Fig. 455.

of any very definite enumeration, since no two cells will be found possessed of a like number of branching tubes. The general arrangement of the tubes is radiate as regards the cells, which forms their common centre. This statement requires some qualification, for not uncommonly a much greater number of tubes arise from one side of the cell than from the other, and these tubes all take one direction. A tube after passing some little distance from the cell will in many instances divide, and each division pass on distinct from its fellow, equalling in size the parent tube. Frequent anastomoses are effected between different tubes arising from the same cells, but far more frequently between those which arise from neighbouring cells. So frequent are the connections that a free communication is established between the various cells and branching tubes throughout the substance of the bone.

So numerous are the connections between the tubes, and immediately between the cells through the tubes, that a fluid introduced into one cell in a bone may find its way into every other cell of the bone. Indeed this does take place, though not from a single cell, yet from the surface of the bone. If, for instance, you place a bone that is dry, and opaque as a consequence of being dry, in spirits of turpentine, in a very little time this bone, before opaque, will become comparatively transparent, and this through the fluid having passed through the tubes into the cells. For, as will be shown, it is the tubes only that open upon the surface of the bone, either the external surface or the surface of the canals for vessels. Indeed, if a thin section of bone be taken and all moisture removed, and spirit of turpentine be added to it, when under the microscope, the passage of the fluid through the tubes may be seen, an experiment suggested by my friend Mr. Bowman.

Besides this relation between the tubes themselves and their cells, they have a very definite relation to the Haversian canals as well as to the free surface of the bone and also to the laminæ.

The position occupied by the cells is between the laminæ, or on the surface of the laminæ; and where concentric laminæ occur, as in the Haversian system, the cells are arranged in circular lines between the laminæ, each line of cells having as an exit common to it and the connecting laminæ the Haversian canal. The flattened sides of the cells are parallel with the circumference of the Haversian canal, while their greater diameter is in the direction of the circular line of the lamina, or with the length of the canal to which they belong. Bone cells so placed send out numerous tubes, which pierce the laminæ at right angles and proceed in great numbers to the vascular canal, into which they enter, there terminating in an open mouth upon the surface; thereby establishing a connection of tube channels between the bone cells of the Haversian system and the canal of the system. (See *fig.* 448.) Although these cells send out many tubes in the above direction, yet others, though comparatively few, take an opposite course, and then establish by anastomosis a connection with the tubes of the surrounding bone cells. This is more particularly seen when we look upon a transverse section of an Haversian system; but if a section taken in the length of an Haversian system be examined, the tubes will for the most part be seen dividing the cells equally in point of number from every part of the circumference of the cell, and of course proceeding in the length of the laminæ between which the cell is placed. As in the transverse section of the Haversian system these tubes that take the longitudinal direction are not seen, so in this section the tubes proceeding directly towards the Haversian canal are but badly shown. So many of the delicate tubes take the direction of the Haversian canals and enter it, that the parietes of each canal at first sight have a radiate appearance, which has led some writers to describe a system of radiate tubes passing through some of the laminæ, but they have failed to trace their connection with the bone cells not far distant. When the cell with its radiating system of tubes is situated near the surface of the bone, the direction of the latter will be mostly towards that surface, unless indeed there is a vascular canal near at hand, in which case many will proceed towards it.

Those cells which are placed in the connecting laminæ send out their tubes tolerably equally in each division, anastomosing freely with the tubes coming from the cells belonging to the Haversian or superficial system of laminæ, and so establish a communication between the cells of the three systems of laminæ. The number of tubes and the size of the bone cells bear to each other no definite proportion; thus a small cell may have many tubes while a much larger one has comparatively few. The number of the cells in a given space is subject to considerable variety, as well as the number of the radiating tubes, though generally the number of tubes will exist in inverse proportion to the number of the cells. Thus in the crania of small birds the cells are of very frequent occurrence, while the tubes connected with each cell are but few. Again, in dense bones of quadrupeds and of man, the cells are less frequent, but the tubes of each cell far more numerous.

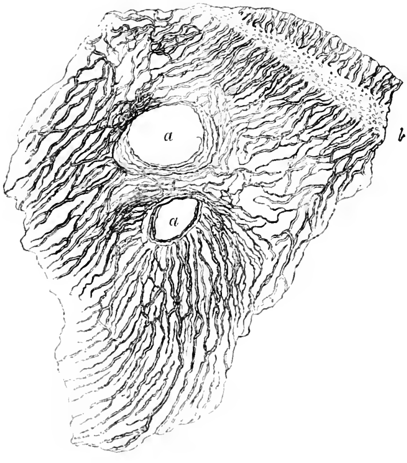
Where the canals for vessels are very numerous the bone cells become more rare, and in some cases they are nearly absent, as shown in *fig*. 451.

From the foregoing description it may be seen that the infinitely numerous tubes everywhere connected amongst the cells, converging at certain points and entering into cells, in fact form these cells; that the cells are nothing more than many tubes coming to a point and losing their individual parietes.

In other cases where the tubes to each cell are not numerous, the cell itself may be compared to a dilatation of those tubes. This view of the subject is borne out by the fact that even in the human subject we find here and there tubes occupying the place of the cells and their radiating tubes, while in certain fish the cells are almost entirely absent and the simple tubes general.

In such instances the tubes hold the same relation to the Haversian canals as do the bone cells where they exist. (See *fig*. 456.)

Fig. 456.



Section of a bone of an osseous fish.

a, transverse section of Haversian canal; *b*, longitudinal section of an Haversian canal with system of tubes opening into it.

The cells when seen by transmitted light, especially in a transverse section of bone, appear perfectly opaque; this has given rise to the opinion that they contain some amorphous salt, and the fact that these same cells become transparent when the bone has been subjected to the action of acid, confirmed observers in this opinion, and that this salt was a salt of lime. When first these observations were commenced I was disposed to hold a like opinion, but further investigation has convinced me that as a rule the cells are empty. I have seen, and that too very frequently, cells which were obviously without contents, and this observation may be repeated in any bone where the cells are tolerably large by making a section in the length of bone, and so parallel with the direction of most of the Haversian canals. By making such a section you expose the cells in their largest diameter, when they may be seen into; whereas if cut through in their narrow diameter they are so deep that they produce complete interference of light, and so seem black, as though filled with some opaque substance.

Again, if turpentine or thin Canada balsam be added to a section quite dry beforehand, the dark cells will become filled with turpentine or balsam, and so become transparent.

The function performed by the bone cells is no doubt that of circulation. Atmospheric pressure would prevent them from remaining empty, and as their openings are always upon a surface where there are bloodvessels, the fluid portion of the blood is probably carried into them. Supposing them once filled with liquor sanguinis, the varying density of the blood itself would produce a slow kind of circulation, even though the contents of the cells remain unaltered, which is not probable.

Cells of smaller form and having branching tubes are to be found in the vegetable world. The shells of various fruits, as the cocoa-nut, peach, common nut, &c. present cells so like those of bone that a section of shell has often been mistaken for one of bone. In this instance they also answer the purposes of circulation.

The growth of bones.—Many experiments have been made to ascertain the mode of growth in bones, but they have given as their results the direction of increase rather than the process of interstitial growth. The experiments alluded to are commonly spoken of as the madder experiments, and were instituted by Du Hamel, Detlif, Hunter, Stanley, Paget, and others.

It was discovered that phosphate of lime acts upon the colouring matter of madder as a mordant. Thus, if phosphate of lime be precipitated from a state of chemical combination in a solution of madder, the colouring matter of the madder is carried down with the phosphate in a state of chemical combination, imparting to the phosphate a red colour, which is not diminished by repeated washing, but gradually fades by exposure to light. But, before this discovery was made, it was found that the bones of some pigs that had been accidentally fed upon madder were rendered red. Attention having been drawn to this curious fact that madder given in the food reddens the bones of the animal, the madder experiments were undertaken, and led to the following results.

If madder be given to a growing animal, and the bones be examined by making a section of a cylindrical bone, a ring of reddened bone will be seen to form the circumference of the bone, and a similar reddened ring to form the parietes of the medullary cavity. If in this experiment the animal had been old, these rings of red would not have been seen, or, if seen, only very faintly. From these two experiments it has been deduced that the bone, or rather the phosphate of lime, which has been deposited during the exhibition of the madder, has alone been reddened.

If, however, after giving madder to a growing animal for a time, its use be discontinued for a while and then be again given, several rings of reddened bone will be observed on making a section of a cylindrical bone, that is, reddened bone will be deposited during the use of the madder, and white bone at the interval of its discontinuance. So that, by the alternate use and disuse of madder, rings of red and of white bone will be formed to a considerable number. From these experiments it has been deduced that bones increase in their diameter by the development of the bone on the surface somewhat in the same manner that a crystal increases in size by additions to its surface.

Mr. Gibson, however, for a while threw some doubts on the value of the madder experiments and the deductions from them, by stating that the serum of the blood had an affinity for the colouring matter of madder superior to that of the phosphate of lime, and that the bone became stained only after the serum had been thoroughly saturated with madder, and more, that the serum, from the discontinuance of madder in the food, or losing the colouring matter, absorbed that existing in the bones.

Mr. Paget has, however, proved that the affinity is far stronger between phosphate of lime and the colouring matter of madder than between serum and the latter. These experiments seem at first sight far more valuable than a closer investigation will prove them to be, as will be seen on considering the following fact, namely, that not only is the surface of the bone with the walls of the medullary cavity tinged red by the exhibition of madder, but also the circumference of every Haversian canal throughout the bone, in fact every surface that lies in contact with a vessel or vessels. The fact that every Haversian canal has its coloured ring had escaped observation, as these experimenters had been limited to the use of the naked eye, whereas the Haversian canals, with their coloured rings, are only seen by the use of the microscope.

It therefore remains for observation to be made upon the effects of consecutive feeding with and without madder, upon the Haversian canals, before any very accurate deductions can be made.

Other experiments have been tried in investigating the growth of bones.

Rings of metal have been lightly fixed round a long bone, which after a while has been found to contain the rings in its medullary cavity, from which it has been inferred that the bone has grown by additions to its circumference, while the medullary cavity has been enlarged by the absorption of the bone forming its parietes. These experiments, which were made by Du Hamel, have been confirmed by Hunter and Stanley.

Experiments of a similar nature have been made to determine the manner of growth in the length of bones. Thus holes have been bored in the tibia of a dog at definite intervals, which intervals, after the lapse of some days, have been found altered in the relative lengths. The intervals near the ends of the bone have increased considerably, while those situated near the centre of the bone have scarcely changed. Mr. Stanley has shown that in some animals the growth is greatest at the distal end, while in other animals it is greater toward the proximal end of a long bone.

In the two experiments which I have related in a previous part of this article the walls of the medullary cavity were as distinctly reddened as the circumference of the bone, and the circumference of each Haversian canal as either. These would therefore prove too much for the theory which supposes that a long bone increases its diameter by the depositions upon its surface and under its medullary cavity by the absorption of the walls. Supposing the idea that phosphate of lime, which is deposited during the exhibition of madder, is alone reddened to be correct, the parietes of medullary cavity should not show colour, as here absorption is supposed to be going on.

From what is already known, I think that the bones are coloured by the madder just in proportion to their powers of imbibition, which will be in inverse proportion to the amount of phosphate of lime which they contain.

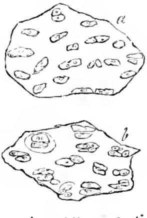
As regards the growth of bone, the laws common to the growth of every other tissue and to the whole body will, I think, be found to hold good. And the growth of these organs will be found to be interstitial, pervading the whole substance, though the action will be more energetic at some points than at others, as the neighbouring organs may require greater length or breadth in one direction than in another.

The younger the bone the more rapid will be its growth, but this law is common to all the tissues. The increase of length of a long bone at the epiphysis must not be confounded with growth of the bone, for here, so long as cartilage connects the shaft with the epiphysis, osseous tissue is being developed; whereas, in speaking of the growth of bones, the increase of the tissue already developed is alone meant.

Of the developement of osseous tissue.—As the developement takes place in cartilage, and as the cartilage undergoes some change previous to its giving place to bone, it will be well to give a slight sketch of the structure of temporary cartilage before going into the formation of the more permanent tissue. The rudimentary condition of cartilage may be best examined in the fœtal chicken, a few days after the commencement of incubation. The exact time for making the observation will be found by taking an egg for examination every six hours, commencing after the eggs have been exposed to the due temperature for thirty-six hours. On the first appearance of the vertebral column, which will present a semitransparent line in the length of the developing fœtus, the whole must be removed with great care to the field of the microscope. This part of the operation requires some care, but with a little management may be successfully performed. I found but little difficulty in removing the delicate object after adopting the following plan. Having, in the first place, placed the egg in a dish of water of sufficient depth to cover it, let the shell be carefully removed; then, by moving the water with the assistance of a camel's-hair brush, take away the albumen so as to leave the yelk free. The point where developement is going on will then be sufficiently conspicuous. At a considerable distance around this the membrane of the yelk should, with a pair of sharp scissors, be cut through, and carefully separated with the aid of a camel's-hair brush and a pair of forceps. This having been effected, the subject for examination will be left on the surface of the yelk, and may, with delicate manipulation with the pencil, be removed to a slip of glass held near it under the surface of the water. Having completed your purpose so far, the glass must be raised very slowly from the water, so that the specimen may not float off, and this being covered with a little thin talc or glass supported at the sides, so that it shall not press upon the embryo to be removed to the field of the microscope. If the specimen be favourable, the semitransparent line of the vertebral column will under a low power appear made up of a vast number of clear colourless oval cells, so closely connected as to leave no appreciable space between the individuals composing the mass. Under a higher power, however, each cell will present a definite outline with a central nucleus or nuclei, and even in some nucleoli. The cells give the appearance of density and clearness of substance, and with their definite and smooth outline present a great contrast to the highly granular cells of developement that surround them. In each vertebra there is some show of a radiate arrangement, for many cells are egg-shaped, and have their small ends placed towards the centre of the growing mass. At this period of the formative process the cells are so close to each other that there is no space for intercellular tissue.

With the growth of the embryo the cartilage advances, and its developement as a perfect tissue is completed by the separation of the cells from each other by the interposition of an intercellular tissue. This latter is transparent and dense, but without traces of definite structure, unless it be a minutely granular tissue. Temporary cartilage is thus shown to be composed of cells having parietes and contents, and intercellular, (see *fig.* 457) or, as some have called it, hyaline substance, through which the cells or corpuscles are equally distributed. In cartilage thus constituted, the developement of bone proceeds. With the commencement of the developement of bone, great changes occur in the arrangement of the cartilage corpuscles as the immediate precedents of ossification. They are no longer equally distributed through the hyaline substance, but are found arranged in parallel columns of variable lengths, in the line of the length of the bone. The corpuscles forming into columns necessarily leave intervening columns of intercellular tissue. A notion has pretty generally prevailed that the corpuscles already formed marshal themselves into this order. I think, however, that on further investigation it will be found that each corpuscle has developed others, and that they have been developed in one direction only, and that towards the line where osseous formation has commenced; for we find that the first perceptible change in

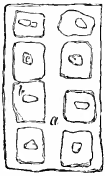
Fig. 457.



a, temporary cartilage, with the corpuscles and intercellular tissue; *b*, temporary cartilage, with the corpuscles forming for ossification.

temporary cartilage on the approach of ossification is that the corpuscles, instead of being solitary, are arranged in groups of variable numbers according as they are near or far off the site of immediate ossification; that they have a linear arrangement, and where there are two or three only this is somewhat semilunar, with the straight edges near each other; and that the greatest diameter is lateral. (See *fig*. 457, *b*.) Moreover, the columns are not continued uninterruptedly through the cartilage, but are broken off, and near their terminations new ones commence, not, however, in a line with the former, but opposite their intercolumnar spaces. (See *fig*. 458.)

Fig. 458.



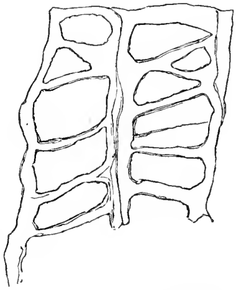
Temporary cartilage, with corpuscle arranged in columns.

a, intercolumnar or cellular tissue; *b*, parietes of the corpuscle; *c*, central cavity of the corpuscle.

Supposing this view of the subject to be correct, as I believe it to be, the growth of a bone in its length admits of easy solution, namely, by the developement of cartilage at the epiphyses.

The formation of columns having commenced, developement in the lines proceeds with rapidity, and the corpuscles composing them hold a different relation to each other at each part of the same column. Thus at the end farthest from the point of ossification the corpuscles are flattened and closely arranged, presenting an appearance not unlike a pile of pence. But as we trace the line down towards the bone, each corpuscle becomes more distinct, is separated from those on either side, becomes itself enlarged, and of nearly equal dimension in each direction. (See *figs*. 458 and 460.) The intercellular tissue becomes distinctly visible between each corpuscle. The space also between the columns, though always considerable, is increased when the corpuscles have undergone the above change. (See *fig*. 459.)

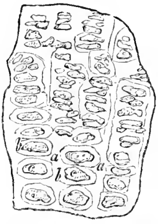
Fig. 459.



Section of the intercellular or hyaline substance, the corpuscle having been removed.

Not only are the described changes in form and relative position observable, but a further remarkable developement takes place in each corpuscle. The parietes of the cell, which at first formed but a small part of the whole, at this latter situation has so far increased in dimension that it forms by far the greater part of the mass, while the central portion, which at first appears to constitute the whole corpuscle, notwithstanding its increase of size, is now to be regarded only as a nucleus, presenting the appearance of a cavity or granular cell, of a form approaching that of a sphere. (See *fig*. 460.)

Fig. 460.

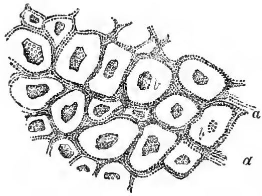


Section of temporary cartilage, which has undergone the last stage towards ossification.

a, intercolumnar tissue; *b*, the enlarged parietes of corpuscle; *c*, central nucleus of the corpuscle.

Cartilage, when it has been subject to the above changes, in the next transition becomes bone. In order to understand this process it will be necessary to bear in mind the following points: first, that the enlarged cartilage corpuscles are arranged in vertical columns; that each column is surrounded by the intercellular tissue, and that each corpuscle is separated from those above and below by a layer of intercellular tissue; and, lastly, that each corpuscle has distinct parietes with central nucleus, or cavity, containing granules or having granular parietes. Osseous tissue is in all instances developed in the form of minute granules, so the earliest appearance of bone in cartilage is marked by the presence of these spherical granules in the intercolumnar and intercellular tissue, which is thereby increased in density and opacity. This constitutes the first stage in the process of the developement of bone, and may be observed by making a thin section of a bone at the point of junction of the bone and cartilage, where the shaft is connected with the epiphysis. (See *fig*. 461.) The granular appearance will be

Fig. 461.



Transverse section of temporary cartilage in the first stage of ossification.

a, a, intercellular tissue ossified; *b*, the transparent parietes of the enlarged corpuscle; *c*, the central nucleus, which in the specimen from which this figure was taken was granular.

increased if a little acid be added to the section; caustic alkali will produce a similar effect. The intercellular tissue having become granular, the parietes of the corpuscles next undergo a similar change, and the central nucleus or cavity can no longer be identified. The accession of granules to the parietes of the corpuscles constitutes the second stage of the process of ossification.

The third stage is an action of a different nature, and is fulfilled in the absorption of the osseous matter interposed between the cells, and also of that portion of the ossified cells which lay in contact with the intercellular tissue of the columns.

By this change, the column, once composed of closed cells, is converted into a tube marked by numerous indentations corresponding in number to the cells which entered into its formation, there being a contraction at the points of junction between the cells. The tube so formed, supposing this condition to be permanent, would have closed ends, and the length would be determined by the ends of the columns of cells from which it was formed. (See *fig*. 462.)

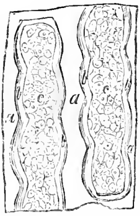
These elongated tubes, I believe with the authors of "The Physiological Anatomy," to be the Haversian canals in their rudimentary state. They do not, however, retain this form of tubes with closed ends, but like individual cells become perforated and communicate with other tubes similarly formed; but as these do not follow each other in straight lines, the openings are formed at the sides of the tubes instead of their ends, so that these communications are at angles with the tubes. These and other openings which are formed between the cells or tubes lying parallel to each other are those Haversian canals in their rudimentary state which traverse bone at right angles to its length, and form anastomoses with the longitudinal Haversian canals, which in bone are by far the most numerous.

In the tubes no trace is left of the central nucleus or cavity of the original cartilage corpuscle; they contain, however, small spherical bodies composed of very minute granules. These are transparent and resemble in appearance those peculiar globules found in the blood and commonly designated lymph globules. (See *fig*. 462).

They are very numerous, and, indeed, almost fill the cavity. They have a red tinge, and constitute almost entirely the mass of red matter found in the interior of all recently formed and forming bone. These bodies were described by Dr. Todd and Mr. Bowman, and they suppose them to be concerned in the developement of vessels, since up to this period of ossification no bloodvessels exist in the forming tissue, but make their appearance so soon as the tubes become pervious.

If a transverse section be made of bone in this stage of its formation, there will be no difficulty in recognising, first, the ossified intercellular tissue, then the ossified parietes of the once cartilage corpuscle, which, being now the lining of the tube, will eventually be the external lamina of an Haversian system; and, lastly, the granular globules contained in the tubes.

Fig. 462.

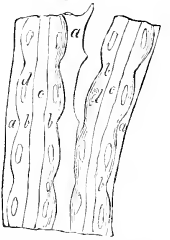


Section of the tubes formed by the cells.

a, intercellular tissue ossified; *b*, ossified parietes of the corpuscles; *c*, granular globules contained in the tubes.

The last point for consideration in the developement of bone is the formation of the bone-cells. Several recent authors consider the cells to be formed from the nucleus of the cartilage corpuscle; I have not been able to confirm their statements, but have been led to entertain a different opinion of their origin. The formation of tubes having been completed, the inner layer formed from the parietes of the corpuscle is at first thin, and, could it be withdrawn entire, would look like a tube formed by the junction of a number of hollow beads. Partial separation may, however, be produced, as seen in *fig*. 463. This state of alternate dilatation and contraction seen in the tube at its first formation is soon lost, and the tube becomes of nearly equal diameter throughout from the filling up of the dilatations by the deposition of osseous matter in the usual granular form. But in this filling up of the dilatations small cells are left, and these are the bone-cells in the rudimentary condition, and form the outer layer of cells in the Haversian system. (See *fig*. 463.) At first it is difficult to distinguish the tubes of the bone-cells, but if a section be taken near the perfected bone, they will be seen in various stages of developement. At this late period of the formation, bone-cells appear in the ossified intercellular tissue, which from the first formed a connection between the systems of tubes, and which in fully formed bone unites the Haversian systems. With this we have bone in its perfect state.

Fig. 463.



Section showing the developement of the bone cells and the separation that may be produced between the ossified intercolumnar tissue and the tissue of the united cells.

a, ossified intercolumnar tissue; *b*, ossified parietes of the united cells; *c*, the Haversian canal in its rudimentary state; *d*, bone cells in their first stage of developement.

From what has been stated it will be seen that the cartilage cell or corpuscle is the first part formed; that this cell generates others; that they form the lining of the primary tube; that the lining becomes the external lamina of an Haversian system: so that the parietes of the cell in the embryo may be considered the element of the laminæ.

Again, the intercellular tissue found in the embryo forms the medium of connection between the cartilage cells or corpuscles, as they are called, between the primary tubes, where bone is developing, and lastly, becomes the bond of union between the Haversian systems.

The foregoing description applies to the growth of the shaft of a long bone in the cartilage connecting it with the epiphysis.

The laws regulating the growth of the epiphysis in the cartilage which unites it to the shaft of the bone are but a slight modification of those which regulate the growth of the shaft. The cartilage corpuscles, however, here form small rounded groups, and ossification proceeds in the intercellular tissue around them, and the groups themselves eventually form a cavity, by which means the spongy head of the bone is formed. The flat bones are developed much as the long ones, the thin edges of these being tipped with cartilage, which developes its cells, and intercellular tissue.

A bone at the time of its development is of equal density through the whole diameter at the point where ossification is just perfected. The arrangement of compact and spongy, as seen in the various bones, is an after process which takes place gradually, and in relation to the individual bones of which the framework of the body is composed.

On considering the process of developement of bone, it will be apparent that the arrangement of cells, intercellular tissue, &c. answers the purpose of giving a definite form and arrangement for the future nourishment of the bone, but that osseous tissue is independent of any particular form. Thus intercellular becomes osseous tissue, as does the tissue of the cells. I wish to lay stress upon this point, as it bears particularly upon the character of certain formations of bone in unnatural situations, or *adventitious bone.*

Ossification of permanent cartilage.—The cartilages of the larynx at an advanced age are liable to become ossified, and in such cases, as the formation of osseous tissue goes on but slowly, the process may be observed with ease. In this case the corpuscles do not develope others as in temporary cartilage where increase of size is required, but retain their usual appearance. While the osseous granules are developed in the intercorpuscular tissue, at first but few of them are seen, and these spherical and isolated; they soon, however, become numerous, and unite, thereby forming an osseous mass. The intercellular or intercorpuscular tissue having advanced in ossification, the corpuscles, or rather their parietes, pass through the same process, and by degrees the whole cartilage becomes converted into bone.

The formation of the individual granules is more readily observed in these cartilages than in any other situation. This form of ossification establishes an interesting and explanatory link of connection between bone and the various osseous plates we find in abnormal situations. For in the latter the spherical granules appear, and these, at first few and isolated, and lying amongst the fibres of the tissue, rapidly increase in number, unite, and form an osseous mass.

Osseous plates occur in various soft tissues as the result of deranged action, where in the healthy condition of the part they are not found. Thus we have osseous plates formed in the coats of arteries, in the pleura, in the diaphragm; also osseous masses in the uterus; and sometimes in the muscular tissue and in the placenta. These plates are all formed in the same manner, namely, by the developement of minute spherical osseous granules, which form into a mass, the shape of which is modified by the form of the tissue in which the developement occurs.

I have examined many of these formations and find them to be composed of true osseous tissue, but not true bone; for they have not the definite Haversian systems, which, formed of osseous tissue, constitute bone. But they have cavities scattered through them; these, however, have no definite shape, but assume all kinds of irregular forms, and though they are no doubt necessary to the vitality of the mass, yet their action cannot be very perfect. Spiculæ of osseous matter are sometimes met with in cancerous tumours, but here it is very rare to find an Haversian system. The osseous plates found in the dura mater are, however, true bone, and are developed like the flat bones. I am decidedly of opinion that these masses are endowed with vitality, and are not mere concretions as some have regarded them, though this vitality is of a low degree.

Formation of osseous tissue in union of fractured bones.—Supposing the subject in which the fractures occur to be young, cartilage similar in every respect to temporary cartilage is produced between the fractured extremities of the injured bone. In the centre of this ossification commences, the process being somewhat similar to ossification of permanent cartilage, or holding an intermediate place between that process and the ossification of epiphyses.

The corpuscles here increase in size but not in number. The ossification commences in the intercellular tissue, and proceeds to the parietes of the cells, thus forming areolæ of bone.

The action may also commence in the cartilage in contact with the fractured surface. This I believe to be the process by which reparation is effected in all cases where union of fractured bones takes place, but my experiments have been confined to young animals.

I have examined various cases where union has not been effected in consequence of the patient's advanced age, and the fracture being at the neck of the femur or of the shaft of the same bone. In these I found no cartilage, and but a scanty amount of condensed cellular tissue. In this latter, however, traces of an attempt at repair may generally be found in the presence of osseous matter in granules or granular masses. In these there is no arrangement of tubes or bone-cells of definite character; indeed these osseous masses are generally small, and sometimes without material density, the individual granules not having firmly united. In fact they resemble in every point adventitious bone.

If in a young animal the fracture be not kept tolerably quiet, the motion between the fractured bone will prevent the formation of cartilage, which seems necessary to the developement of bone, and here, therefore, osseous masses will alone present themselves. This fact is very interesting in a surgical point of view, and might be treated more at length; but having given a detailed account of the developement of bone and of the distinction to be made between true bone and adventitious osseous tissue, I shall conclude the article.

(J. Tomes.)

OVARY.—See Supplement.

OVUM.—See Supplement.

PACHYDERMATA.—An extensive group of herbivorous quadrupeds, constituting a distinct order of the class Mammalia, generally remarkable for their ponderous bulk and unwieldy appearance, and seemingly forming the transition between the gigantic Cetacea, which from their size are only adapted to an aquatic existence, and the vegetable-eating Mammals of strictly terrestrial habits. Even the localities where they are met with would seem to indicate that they constitute such a connecting link, seeing that their most typical forms are peculiarly adapted to be occupants of the river and the marsh, from the Hippopotamus, that might almost be considered an aquatic animal, to the Tapirs and the Hog, which still love to wallow in mud although they approximate in their habits to the ruminating quadrupeds. At the present day the order Pachydermata contains but few genera, and these for the most part embrace a very limited number of species. But in former periods of the history of our globe they must have existed under much greater variety of form, seeing that the tertiary deposits yield to the geologist, in abundance, the remains of very numerous genera now totally extinct, to the list of which modern researches are adding day by day; it is indeed more than probable that many of the existing races will speedily perish, for the hand of man is against them, and the bullet and the spear are doing their work of extermination rapidly, so that the Tapir and the Elephant, like the Palœotherium and the Mastodon, may soon be classified with extinct existences.

The order of Mammalia under consideration is usually divided into Proboscidians, including such Pachydermata as are provided with a proboscis and tusks, of which the Elephant is the only existing example, and into Ordinary Pachydermata, which are unprovided with a proboscis, and characterized by possessing four, three, or two large digits on their feet, which are cased in horny hoofs—the last group being distinguishable from the Ruminantia by the simple construction of their stomachs, although closely approaching them in many points of their economy. The above division, however useful to the zoologist, is nevertheless by no means based on nature, the proboscis of the Elephant being only a maximum

Fig. 464.

degree of developement of the snout of the Pig and the semi-proboscidean nose of the Tapir.

The following genera of Pachydermatous Quadrupeds have been distinguished by naturalists, many of which are still in existence, but the majority are met with only in a fossil state, the names of the latter being printed in italics.

Elephas, (*fig.* 464.)	Hippopotamus
Mastodon	*Toxodon*
Dinotherium	*Coryphodon*

Sus	

Osseous system.—The skeleton of the Pachydermata is generally remarkable for the massive character which is conspicuous in every region, indicative, at a glance, of the ponderous strength and generally inactive habits of the animals belonging to this order; but inasmuch as they are destined to obtain their food under very various circumstances, which demand a corresponding diversity of structure in different parts of their bony framework, some detail will be necessary in adverting to this part of their economy.

Cranium.—The cranium of the Elephant, the only living genus of Proboscidian Pachyderms, is quite unique in its external configuration, and from its vertical elevation confers a remarkable aspect of sagacity to the animal; its intelligence, however, although really surprising when contrasted with the stupidity of other genera belonging to this class of quadrupeds, has doubtless been much exaggerated in consequence of its imposing appearance. This peculiar contour of the skull depends upon several circumstances having nothing whatever to do with cerebral developement, but being entirely dependent upon mechanical arrangements required to support the enormous tusks that project from the upper jaw, and to give origin to the muscles of the proboscis, a nasal apparatus here only met with in a state of complete developement. The extreme shortness of the bones of the nose, the nearly vertical position of the upper maxilla and *ossa incisiva*, and the swollen vault of the forehead produced by an excessive enlargement of the frontal sinuses, (*fig.* 466,) which gives extent of surface to the exterior of the skull, all concur to mask the real condition of the cranial cavity, which, as is easily seen in the next figure, (*fig.* 465,) occupies but a very small portion of the posterior and central portion of this gigantic cranium.

The general character of the individual bones of the cranium and their modifications in the principal Pachydermatous races will be understood from the appended figures better than from any lengthened description.

The *occipital bone* is very extensive, forming by itself the entire posterior wall of the cranial cavity, and even in the Elephant advancing considerably upon its upper surface, where at an early period it becomes so firmly consolidated with the parietals, and these again with the frontals and temporals, that the whole roof of the skull appears to be formed of one bone. In the hog tribe, the Hippopotamus and the Tapir, it terminates superiorly in an abrupt and broadly expanded crest, into which the muscles of the neck are inserted; and not unfrequently the deep fossæ and prominent ridges visible upon its posterior aspect testify to the massive strength required in this part of the muscular system, either to

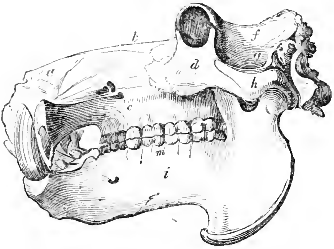
support the unwieldy head or to tear up the ground in search of food, as the hog tribe do with their powerful snouts. In the young animal this bone always consists of four separate pieces—a basal, two lateral, and a superior occipital (*fig.* 471, *c* 1, *c* 2, *c* 3 :) but these soon become inseparably united into one mass.

Fig. 467.



Skull of Hippopotamus.
Letters as in Fig. 465.

The *parietal bones* (*figs.* 465, 467, 468, 471, *f*) are moderately extensive, covering the superior and lateral portions of the skull. In the young animal they are always separated by a mesial suture, (*fig.* 469, *b*, *b*,) but in the adult are united by the obliteration of this suture into one piece, so as to appear but a single bone; a provision, no doubt, for admitting the enormous force of the temporal muscles to be exerted without danger of divaricating the two lateral halves, which might otherwise be torn asunder at the line of junction. In the Tapir there is a lofty interparietal crest, giving great additional surface for the origin of the temporal muscles.

The *frontal bones* are of very great extent, and besides enclosing the anterior part of the cranial box, form a large proportion of the orbital cavity. In the young animal (*fig.* 469, *a*, *a*) they are invariably two in number, separated by a suture along the mesial line, and in the American Tapir this separation is permanent; but generally they become consolidated at an early age, leaving no trace of their original separation.

The *æthmoid* is, in the Pachydermata, of very considerable size, proportioned to the acuteness of the sense of smell with which these animals are gifted. The cribriform plate holds a position exactly similar to that which it presents in the human subject, implanted between the frontal and sphenoid bones, and testifies, by its great extent of surface and the numerous foramina which pierce it, that the olfactory organs are highly developed. Towards the nasal surface, likewise, the œthmoidal cells and

Occipital bone of a young Boar, shewing its division into four pieces.

In the above three figures the parts indicated are as follows :—*a, a,* frontals ; *b, b,* parietals ; *c, c,* 2, *c* 2, *c* 3, occipital ; *d,* temporal ; *e,* lateral processes of occipital bone ; *f,* sphenoid ; *g,* supra-orbital plate of os frontis ; *h,* os lacrymale ; *i,* jugal bone ; *k,* superior maxillary ; *l,* intermaxillary ; *m,* nasal ; *n,* inferior maxilla ; *o,* ossified nasal cartilage ; *p,* palatine.

turbinated laminæ are very large, so that the delicacy of the sense with which they are connected is evidently only inferior to that of the carnivorous quadrupeds.

The *sphenoid* occupies the same position as in the skull of Man, and in the hog tribe is very similar in its shape and the general arrangement of its processes to the human. In the Elephant the anterior and posterior clinoid processes are but slightly developed, so that the base of the cranium internally has a very flat appearance, whilst externally, such is the enormous developement of the sphenoidal cells, that they stretch on each side beneath the alæ minores almost along their whole length and mask the pterygoid processes, so as to give a very peculiar appearance to the base of the cranium.

The bones of the face are remarkable for their massive developement, but as their position is sufficiently indicated in the next woodcuts, it would be useless to particularize them further.

Ribs and sternum.—The thoracic cavity throughout all the Pachydermatous genera is enormous in proportion to the great bulk and excessive weight of the viscera. The ribs, in fact, are continued backwards almost to the pelvis, and from their extraordinary size and

Fig. 472.

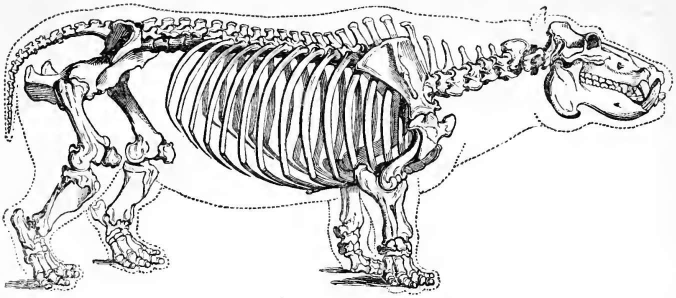
Letters as in figure 465.

Fig. 474.



Skeleton of Hippopotamus.

breadth constitute a kind of osseous case, enclosing a considerable portion of the abdominal cavity, and calculated to give origin to muscles of power proportioned to its ponderous contents.

In the *Hyrax*, dissected by Pallas, there were twenty-two ribs on the left side and only twenty-one on the right: of these seven were true ribs, six false attached to the sternum by the intervention of costal cartilages, and the rest merely imbedded in the muscles of the flanks. The *sternum* consisted of six pieces, of which the last or ensiform was further prolonged by a spathulate cartilage.

In the *Tapir* the ribs are twenty in number on each side, whilst there are but four lumbar vertebræ. The Elephant, likewise, has twenty pairs of ribs and only three lumbar vertebræ. The Rhinoceros has nineteen pairs of ribs, and the Hog only fourteen.

The *sternum* is of considerable length and compressed laterally. In many genera, moreover, it is prolonged in front to a considerable distance, in order to allow more ample space for the attachment of muscles.

Anterior extremities.—The limbs of the Pachydermata are necessarily constructed more with a view to ensure strength adequate to sustain their ponderous bulk than to permit of agile and active movements. The smaller genera, indeed, such as the Suidæ, have their bones so arranged as to permit of considerable fleetness in running, but in the more colossal genera the condition of the extremities secures support at the expense of speed, and flexibility is sacrificed to solidity and firmness.

Scapula.—The shoulder-blade of the Elephant, independently of its size, might be distinguished from that of any other living animal by the following circumstances. When *in situ*, its posterior side, which is deeply concave, is by far the shortest of the three, while the anterior and spinal costæ are of nearly equal length. In consequence of the preceding circumstance this scapula is broader in proportion to its length than that of any other large quadruped, and, moreover, the spine of this bone, besides its acromial process, has towards its middle a broad sickle-shaped projection, looking backwards and spreading over the infra-spinatus muscle. In all other Pachydermata the shape of the scapula is that of an elongated triangle, with the angles of the base much rounded off and the spine very short in proportion to the extent of the dorsum; nevertheless, in the Rhinoceros there is a falciform process projecting from the spine something like that of the Elephant, and both in the Hippopotamus and the Tapir rudiments of a coracoid process. The scapula of the Tapir (*fig.* 475) is also remarkable for a deep and almost circular notch between the rudimentary acromion and its anterior costa.

Clavicle.—None of the Pachydermata have the slightest rudiment of a clavicle, an arrangement which permits the anterior shoulders to be closely approximated beneath the thorax, and thus brought nearer to the centre of gravity.

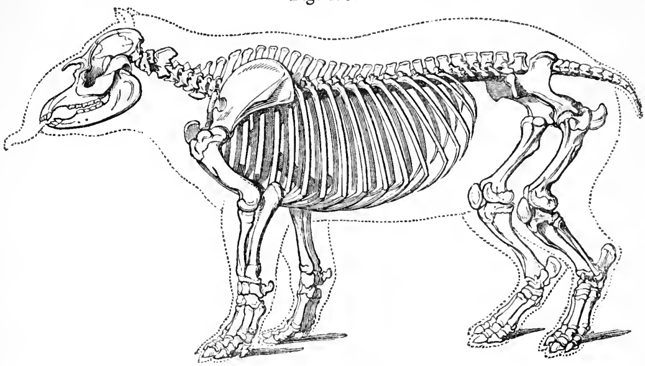
Humerus.—The humerus is in all cases short, massive, and remarkable for the size and strength of the ridges and prominences for the origin and insertion of the muscles connected with it. The head of the bone which articulates with the scapula is very flat, and although large, forms but a very small proportion of its scapular extremity, the rest being made up of enormous protuberances, to which are affixed the muscles of the shoulder. (*Figs.* 474 and 475.)

The lower articulating surface is a simple pulley, articulating with the conjoined heads of the radius and ulna, so as to admit of flexion and extension only, no movements of pronation or supination being here admissible.

The humerus of the Elephant (*fig.* 464) is distinguishable from that of all other quadrupeds by the prodigious extent of the external condyle, which extends upwards nearly one-third of the length of the bone, where it terminates abruptly so as to give a square form to this part of the bone.

Radius and ulna.—As the position of the fore-arm in the Pachydermata is permanently that of pronation, no arrangement has been made in any instance to articulate the radius with the ulna by means of a moveable joint, a certain degree of elasticity (the result of ligamentous connection) being all the motion allowed even where the separation between the two bones is most complete. Sometimes, indeed, as in the case of the Hippopotamus and some of the hog tribe, the two bones of the fore-arm are completely consolidated into one mass, the only vestiges of their having been originally distinct being the indication of a suture near the distal extremity of the fore-arm and a deep groove running along the middle third of the bone for the lodgement of the inter-osseous artery. In the Rhinoceros and Tapir, (*figs.* 475

Fig. 475.



Skeleton of American Tapir.

and 476,) however, these bones remain permanently distinct, the elbow-joint being formed by the radius in front, which articulates with both condyles of the humerus and the ulna posteriorly, which completes the articulation. At their distal extremity the radius lies in front and to the inner side of the ulna, with which it is either anchylosed or immoveably connected by ligaments, both assisting to form the radio-carpal articulation. In the Elephant, the arrangement of these bones is very curious and perhaps unique: the upper head of the radius is firmly fixed between two projections in front of the head of the ulna, and assists in forming the elbow-joint articulating with the outer condyle of the humerus only. It then passes obliquely downwards across the anterior face of the ulna to its distal extremity, where it expands into a broad articulating surface, and assists almost coequally with the ulna in forming the carpal joint.

Carpus.—The bones of the carpus are chiefly remarkable for their large dimensions; they are, however, always distinct and generally the same in number as in Man, although from their altered shape they little conform to the names bestowed upon them in the human subject. The first row, consisting of the analogues of the scaphoid, the lunar, the cuneiform, and the pisiform bones, is firmly connected by ligaments with the distal extremities of the ulna and radius to form the wrist-joint, which, however, is here only capable of the movements of flexion and extension. The second row consists of the representatives of the trapezium; the trapezoid, the os magnum, and the unciform bones support the metacarpus and are generally quite distinct, although occasionally two or more of them are consolidated into one mass.

In the Rhinoceros, which has but three toes, the *trapezoid*, the *os magnum*, and the *unciform bones* each support a single metacarpal bone. The *trapezium* is totally wanting, but there are two supernumerary pieces in connection with the scaphoid and unciforme.

Metacarpus.—The metacarpal bones are generally short and excessively robust, their number of course corresponding with that of the toes. Thus in the Elephant there are five, and in the Hippopotamus, Hog, and Tapir only four, which are small and extremely massive in proportion to the weight they have to sustain. In the genus *Sus*, where the whole burden of progression is thrown upon the two middle toes, and a considerable degree of activity is permitted, the corresponding metacarpal bones are much elongated, and far surpass in size and strength those which support the external and internal fingers, which have rather the appearance of appendages to the outer and inner sides of the metacarpus, than bones articulated with the carpal series.

The metacarpus in the Rhinoceros consists of only three bones conformable to the number of fingers.

Phalanges.—The Elephant alone of all the Pachydermata has five complete fingers; but, although the bones are thus perfectly developed, they are so concealed in the living animal by the hoof and overhanging skin of the fore-foot, that such a condition of this part of their skeleton would hardly be suspected.

In the ungulate tribes, which have only four fully formed fingers, there is still a little bone representing the rudiment of a thumb, although in the generality of artificial skeletons this ossicle is wanting. In the *Suidæ* the two lateral fingers are much shorter than the two middle ones, so that in walking the former do not touch the ground at all; they are, however, quite complete as relates to the number of their phalanges; and the last phalanges of all the toes are moreover moulded to the shape of the horny roof which covers them, a circumstance in which they differ remarkably from the larger genera.

Pelvis.—The pelves of the larger genera are of enormous size, accommodating themselves in this respect partly to the prodigious masses of muscle to which they give origin, and partly to the monstrous capacity of the abdominal cavity. In the *Elephant* and *Rhinoceros* the ossa ilii are very broad, rounded anteriorly and concave towards the abdomen. In the Tapir, the ilium has somewhat the form of the letter T, one branch being articulated with the sternum, while the neck of the bone forms the handle. The pelvis of the Hog very nearly approximates in shape that of carnivorous quadrupeds.

Femur.—The femur of the *Elephant* (*fig.* 464) is remarkable for the simplicity of its shape, which has some resemblance to that of the human skeleton, owing to its general smoothness and the absence of those strong crests and ridges which characterise it in most other gigantic quadrupeds. In all other tribes of the Pachyderms these bones are short, straight, and flattened in the middle, presenting upon the outer border a wide and prominent ridge terminating inferiorly in a hook-like process, which, as well as the trochanter major, is in the case of the Rhinoceros excessively prolonged.

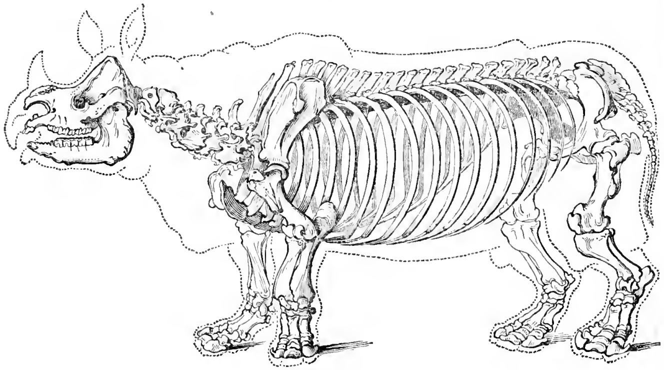
Tarsus.—The bones of the tarsus are similar both in number and arrangement to those of the human skeleton. The *astragalus* is of great size, and all its articulating surfaces very extensive so as to afford a wide basis of support. The *calcaneum* is likewise remarkably prominent and massive.

Metatarsus.—The metatarsus is in the Elephant made up of five distinct bones, of which, however, the external one is but imperfectly developed. In all the other Pachydermatous genera there are only four metatarsal bones corresponding with the number of the toes. Of these the two central ones are far the largest, and sustain alone the entire weight of the hinder part of the body, seeing that the most external and most internal toe of each foot scarcely reaches the ground; and at length in the *Suidæ* the metatarsal bones of these toes become reduced to mere rudiments appended to the sides of the foot, and serve less as organs of support than as appendages given to prevent the creatures so organized from sinking into the marshy soils or soft mud, which they mostly frequent as though to testify the intermediate position which they occupy between the aquatic and terrestrial Mammalia.

Phalanges.—The number of toes upon the hind foot of the *Elephant* is five, each of them, with the exception of the outer one, consisting of three short and massive phalanges; but the external toe is represented by a single massive and irregular-shaped piece. In the living animal all these bones are so encased in the thick skin covering the sole, that the division of the foot is only indicated by the prominent extremities of the toes.

The skeleton of the Elephant is, indeed, quite peculiar in form, so that there is not a single bone or extremity of a bone which may not easily be distinguished from that of any other animal; and it may likewise be remarked that many of the bones of the Elephant more nearly resemble those of the human species than the analogous ones of any other quadruped, especially of the larger inhabitants of this part of the world, such as oxen or horses. As examples of this, may be pointed out the atlas, all the cervical vertebræ, and the bodies of the dorsal vertebræ; the scapula and pelvis on account of their great breadth, the femur from its length and the simplicity of its shape, the astragalus, the os calcis, and all the bones of the metacarpus and metatarsus. It is, therefore, scarcely to be wondered at that even professed anatomists, who had never examined the skeleton of the Elephant, have sometimes mistaken the bones of this animal for the fossil remains of human beings, and consequently of giants.

Fig. 476.



Skeleton of Rhinoceros.

In the *Hippopotamus*, the *Rhinoceros*, and the *Tapir*, the separation of the toes is more apparent externally, but still the phalanges, which are three in number to each of the four toes, are excessively strong and bulky when compared with their length. A kind of gradation is likewise to be traced through these genera, whereby the foot of the Elephant becomes gradually transformed into the cloven hoof of the hog tribe, owing to the progressive diminution in size of the inner and outer toes, and the gradual conversion of the terminal phalanges of the central toes into that prismatic form which adapts them to fit the horny envelopes that encase them like shoes.

Throughout all the hog genera the weight of the body is entirely supported on the two central digits, the bones whereof are proportionally strong and well developed, while the phalanges of the inner and of the outer toe, which do not touch the ground, remain permanently of very rudimentary size.

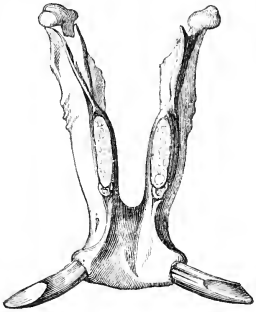
Teeth.—In no order of Mammiferous animals do the teeth present so much diversity of structure and irregularity of disposition as among the Pachydermatous races; it will be therefore necessary, in adverting to this part of their economy, to describe the principal modifications which the dental organs assume in different genera, before we proceed to investigate the manner of their formation; and this we do more willingly, because from the character and arrangement of the teeth we can alone satisfactorily determine what have been the habits of extinct genera, the list of which is already considerably more extensive than that of living forms. Professor Owen, to whose labours in this department science is already so deeply indebted, has in his recent work on the Comparative Anatomy of the Teeth* examined this part of our subject with all the minuteness required for geological researches, and from his kindness we are enabled to lay the following abstract before our readers.

In the genus Sus, the wild progenitor of our domestic breeds of Hogs, Sus scrofa, the complete set consists of forty-four teeth, viz.—

Incisor.	Canine.	Premolar.	Molar.
5 . 3	1 . 1	4 . 4	3 . 3
3 . 3	1 . 1	4 . 4	3 . 3

In the wild Boar both the upper and lower canines curve forwards, outwards, and upwards; their sockets inclining in the same direction, and being strengthened above by a ridge of bone which is sometimes extraordinarily developed, these teeth become converted into most formidable weapons. These teeth, which have the character of true tusks, are three-sided; the broadest convex side being directed obliquely inwards and forwards, while the outer and posterior sides are nearly flat; and the hinder surface being destitute of any covering of enamel; whilst the two other sides are encased with that material, the tusk wears obliquely from behind upwards and forwards to a point, while its posterior margins present enamel edges that are always sharp and trenchant. Each of these tusks in the lower jaw

Fig. 477.



of the German wild Boar will measure eight inches in length along its curve, and in the wild Boars of Assam they have been noticed measuring one foot, so that when wielded by such strong and brawny muscles as those of a Hog's neck, it is easy to conceive that terrific wounds may be inflicted by such instruments.

In the Baberoussa or "Horned Hog" the developement of the canines is still more extraordinary. Those of the upper jaw seem as if their sockets had been pulled out or produced from the alveolar border of the upper maxillary bone, and then abruptly bent upwards, giving the tooth a direction upwards and backwards. The tooth pierces the integuments of the upper lip like a horn, and its growth being unchecked by any opposing tooth, sometimes forces the lip again through the integument and into the substance of the skull. The lower tusks have the ordinary direction, but rise rather more vertically and much higher than in the wild Boar. These strangely situated teeth are well adapted by their position to defend the eyes and assist in the act of forcing the head through the dense entangled underwood of a tropical forest, as suggested in Home's Comparative Anatomy, vol i, p. 221, but their use has not been determined by actual observation.

In the next group of Pachydermata (*Chæropotamidæ*) the dental formula of the existing type of the family Dicotyles, the *Peccari*, is as follows.

Incis.	Canine.	Premolar.	Molar.

3 . 3	1 . 1	3 . 3	3 . 3

The upper canines are moderately long, narrow, and compressed, with an entire covering of enamel; while the lower are long, slightly curved, and have no enamel posteriorly. To this type of dentition belonged the *Hyracotherium* and the *Chæropotamus*, both extinct genera, the former having been about half the size of the existing Peccari, while the latter was about one-third larger. The *Hippophyus*, likewise an extinct genus, found in the Himmalayan

* Odontography, Bailliere, 8vo. 1845.

tertiary deposits, and of about the size of the Chæropotamus, appertained to the same family.

A third kind of dentition characterizes the *Hippopotamidæ*, in which the tendency to excessive and, as it may be termed, monstrous developement of the canine teeth, for which the typical Suidæ are remarkable, affects both the canines and the incisors. Of this group the only existing representative is the Hippopotamus of the great rivers of Africa. In the Hippopotamidæ the implanted base of each of the incisive and canine teeth is simple and excavated for a large persistent matrix, which causes their perennial growth by constantly adding materials at the base of each to replace what is worn from their abraded extremities. The direction of the abraded surfaces is in part provided for by the partial disposition of the enamel; in the upper median incisor this is laid upon the fore and outer part of the tooth, while in the lateral incisor there is a narrow strip of enamel along the convex side of the tooth. The enamel is soon worn away from the crowns of the lower incisors, but it is persistent in the canines, where it extends to the end of the implanted base; in the upper canine being laid upon the posterior and outer, but not on the fore part, whilst its position is reversed upon the inferior canine.

The extinct genera of Hippopotamoid Pachyderms at present discovered are the *Hexaprotadon*, the *Merycopotamus*, and the *Anthracotherium*.

Perhaps one of the most singular forms of the dental apparatus hitherto met with among Pachydermal Quadrupeds is that of the *Toxodon*, a large extinct genus, represented by two species both equalling the Hippopotamus in size, whose remains have been discovered by Mr. Darwin and M. de Angelis in the recent tertiary deposits of South America. The teeth of the Toxodon consisted of molars and incisors, separated by a long diastema or toothless space. In the upper jaw the molars were fourteen in number, seven on each side, and the incisors four, which latter differ in their proportions in the two species. In the lower jaw there were six incisors and *twelve* molars.

All the molar teeth are long and curved and without fangs, as in the Wombat and most of the herbivorous species of the Rodent order: in existing races, however, with curved grinders, as the Aperea or Guinea-pig, the concavity of the upper grinders is directed outwards, the fangs of the teeth of the opposite sides diverging as they ascend in the sockets; but in the Toxodon the convexity of the upper grinders is outwards, as in the Horse, but with so much greater curvature that the fangs converge and almost meet at the middle line of the palate, forming a series of arches capable of resisting great pressure. It was this structure which suggested to Professor Owen the generic term conferred by him upon this most remarkable extinct Mammal.*

Of the upper incisors there are two small ones situated in the middle of the front of the intermaxillaries, and exterior to these two large ones, in close contiguity with the small incisors, which they greatly exceed in size.

The sockets of the two large incisors extend backwards in an arched form, preserving an uniform diameter, as far as the commencement of the alveoli of the molar teeth; the curve which they describe is the segment of a circle, the position, form, and extent of the sockets being such as are only found in those of the corresponding teeth of the Rodentia among existing Mammalia; and it may likewise be inferred that the pulp which formed them was persistent, and that the growth of those incisors, like those of the Rodentia, continued throughout life. The six lower incisors were all of nearly equal size, hollow at their bases, and partially coated with enamel, like the "dentes scalprarii" of the Rodentia; they differed, however, from these in having a prismatic figure, like the incisor teeth of the Sumatran Rhinoceros, or the tusks of the Boar. That they were opposed to teeth of a corresponding structure in the upper jaw is proved by their oblique chisel-like cutting edge.

The name of *Elasmotherium* has been given to an extinct Pachyderm with fangless molars, surpassing the Toxodon in size, and of which only the lower jaw and its dentition is yet known; but the characters of the teeth are sufficiently remarkable, owing to the beautiful undulating folds into which the enamel is thrown, a circumstance from which the name of the genus is derived.* The original jaw, preserved in the Museum of Moscow, is unique, and was discovered in the frozen drift or diluvium of Siberia.

In the *Rhinocerotidæ*, including the typical *Rhinoceros*, the extinct *Acerotherium*, which had no horn, and the equally hornless small existing genus *Hyrax*, the molar teeth are implanted by distinct roots. There are no canines; and as to the incisors the species vary, not only in regard to their form and proportions, but also their existence, and in the varieties of these teeth we may discern the same inverse relation to the developement of the horns which is manifested by the canines of the Ruminants. Thus the two-horned Rhinoceroses of Africa, which are remarkable for the great length of one or both of the nasal weapons, have no incisors in their adult dentition, neither had that great extinct two-horned species (*Rh. tichorinus*), the prodigious developement of whose horns is indicated by the singular modifications of the vomerine, nasal, and intermaxillary bones in relation to the firm support of those weapons. The Sumatran bicorn Rhinoceros combines with comparatively small horns moderately developed incisors in both jaws, and the same teeth are present in the nearly allied two-horned Rhinoceros called after its discoverer Schleiermacher.

The incisors are well developed in both the existing unicorn Rhinoceroses, *Rh. Indicus* and *Rh. Sondaicus*, but they attain their largest dimensions in the singular extinct hornless species, the Rh. incisivus of Cuvier. In the

* Τόξον, arcus; ὀδοὺς, dens.

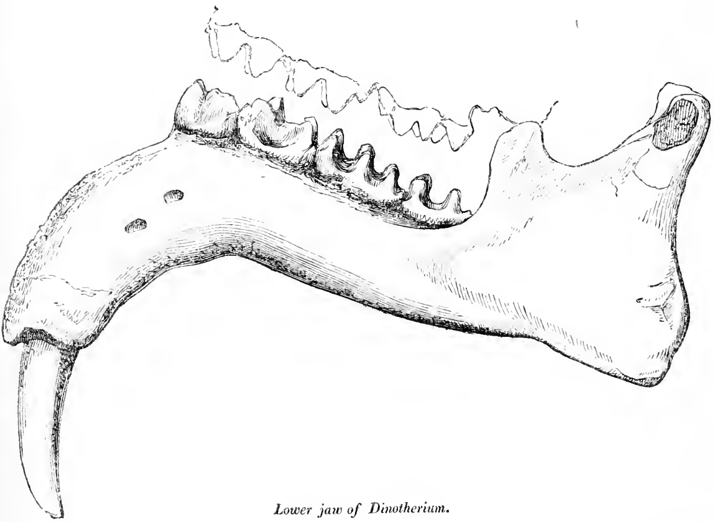
* Ἔλασμα, a plate; θηρίον, a beast.

adult Rhinoceros no traces of canine teeth are visible, but Professor Owen succeeded in detecting their existence in a rudimentary condition in the mature fœtus of the Rhinoceros Indicus, although both the teeth and their sockets disappear at a very early age.

The vast hiatus which in the series of existing Mammals divides the Rhinoceros from the Tapir, and this from the Elephant, was once filled up by interesting transitional species, which have long become extinct, such as the *Palæotherium* and the *Macrauchenia*, the *Lophiodon*, *Coryphodon*, and others requiring no particular notice in this place. But that most extraordinary of extinct Pachyderms, the *Dinotherium*, must not be so lightly passed over, inasmuch as its dentition appears to have been quite unique in character, as may be seen on reference to *fig.* 478, which represents the lower jaw of this gigantic quadruped. From this it will be seen that the molar and premolar teeth resemble in some respects those of the Mastodon; but the great peculiarity of the Dinotherium exists in its tusks projecting from the lower jaw. These tusks are two in number, implanted in the prolonged and deflected symphysis of the lower jaw, in close contiguity with each other, and having their exserted crown directed downwards and bent backwards, while their deeply implanted base is excavated by a wide and deep conical pulp cavity, like the tusks of the Mastodon and Elephant. No such tusks nor germs of such have yet been discovered in the upper jaw, so that it is highly probable that this gigantic Pachyderm was of aquatic habits, like the Hippopotamus, and that its tusks served to detach and tear up by the roots the aquatic plants upon which it fed, as well as for weapons of defence or combat.

No family of Mammalian Quadrupeds has suffered more from the destructive operations of time than that of the Proboscidian Pachydermata. Two species only, the Indian and the African Elephants, continue to represent this type in the Mammalian series of the present day; whilst those that manifested the modifications of the dental system which gradually reduce the complexity of the Elephantine dentition to the comparative simplicity of that of the Dinothere and Tapir, have long since been blotted out of the series of living beings. Of these the gigantic *Mastodons* are the most conspicuous — animals nearly allied to the existing Elephants, but differing from them in the construction of the grinding surfaces of their molar teeth, which had their crowns studded with conical eminences more or less resembling the teats of a cow—whence the generic name is derived.* In addition to these grinding teeth the Mastodons were provided with two enormous tusks, resembling those of the Elephant, implanted into the intermaxillary bones of the upper jaw; and moreover those Mastodons with the more simple and typical molar teeth likewise manifest the Dinotherian character in having tusks in the lower jaw of the adult male and in the young of both sexes.

Fig. 478.



Lower jaw of Dinotherium.

The dentition of the Elephant, the sole surviving genus of the great Proboscidian family, consists of two long tusks, one situated in each of the intermaxillary bones, and of large and complex molars in both jaws. Of the

* Μαστὸς, a nipple; ὀδοὺς, a tooth.

latter there is never more than one wholly, or two partially in place and use on each side at any given time; for like the molars of the Mastodons, the series is continually in progress of formation and destruction, of shedding and replacement, and in the Elephants all the grinders succeed one another horizontally, from behind forwards, none being displaced and replaced by vertical successors or premolars.

The total number of teeth developed in the Elephant Professor Owen believes to be

$$\text{Incis.}\ \frac{2\ .\ 2}{0\ .\ 0}\ \text{Molars}\ \frac{6\ .\ 6}{6\ .\ 6} = 28,$$

the two large permanent tusks being preceded by two small deciduous ones, and the number of molar teeth which follow each other being at least six; but Mons. Corse was of opinion that this replacement of teeth is repeated at least eight times in the Indian Elephant, which would consequently have thirty-two teeth successively taking their respective places in the jaws.

The deciduous tusk makes its appearance beyond the gum between the fifth and seventh month; it rarely exceeds two inches in length, and is about a third of an inch in diameter at its thickest part, where it protrudes from the socket; the fang is solidified, and contracts to its termination, which is commonly a little bent and is considerably absorbed by the time the tooth is shed, which takes place between the first and second year.

The socket of the permanent tusk in a new-born Elephant is a round cell about three lines in diameter, situated on the inner and posterior side of the aperture of the temporary socket. The permanent tusks cut the gum when about an inch in length, a month or two usually after the milk teeth are shed. The widely-open base of the tusk is fixed upon a conical pulp, which, with the capsule surrounding the base, progressively increases in size, stimulates a concomitant increase in the capacity and depth of the socket, which cavity soon obliterates that of the deciduous tusk.

These incisive teeth of the Elephant not only surpass other teeth in size, as belonging to a quadruped so enormous, but they are the largest of all teeth in proportion to the size of the body, representing in a natural state those monstrous incisors of Rodents which are the result of accidental suppression of the wearing force of the opposite teeth.

The molar teeth of the Elephant are remarkable for their great size, even in relation to the bulk of the animal, and for the extreme complexity of their structure. The crown, of which a great proportion is buried in the socket, and very little more than the grinding surface appears above the gum, is deeply divided into a number of transverse perpendicular plates, consisting each of a body of dentine, coated by a layer of enamel, and this by a less dense bone-like substance which fills the interspaces of the enamelled plates, and here more especially merits the name of cement, since it binds together the several divisions of the tooth before they are fully formed and united by the confluénce of their bases into a common body of dentine.

The manner in which these complex teeth are formed is a subject of great interest, and has been ably investigated by many celebrated anatomists, particularly by the two *Campers*, father and son, M. Corse, Robert Blake, and John Hunter, whose splendid preparations illustrative of the process are contained in the Museum of the Royal College of Surgeons in London. It is to Cuvier, however, we are indebted for the most complete and luminous exposition of this important piece of physiology, as may be gathered from the following account extracted from his great work, "Recherches sur les Ossemens Fossiles." "The molar tooth of the Elephant, like every other mammiferous tooth, is formed in the interior of a membranous sac, now generally called the *capsule* of the tooth. This capsule has in the Elephant a rhomboidal form, and is closed on all sides, excepting the small openings for the passage of nerves and vessels. It is lodged in a bony cavity of the same shape as itself, excavated in the maxillary bone, which afterwards forms the socket of the tooth."

"It is, however, only the external lamina of the capsule which is thus simple in its arrangement, the inner lamina being, as in all other herbivorous animals, thrown into numerous folds, as will be understood when we have described the pulp upon which the tooth is formed."

"This pulp has in every animal its peculiar arrangement. To represent that of the Elephant, we must imagine that from the bottom of the capsule as from a base, there arise numerous parallel and transverse walls which mount upwards towards that part of the capsule which is placed next to the gums. These little walls are only adherent to the floor of the capsule, their opposite extremity or summit being free from all adherence."

"The free summit is much thinner than the base, so that it might be called the edge, and is moreover deeply cleft in many parts, so as to form numerous sharp points and indentations. The substance of these little walls is soft, transparent, and very vascular, containing apparently much gelatine: it becomes hard, white, and opaque in spirits of wine."

"It will be now easy to understand the manner in which the inner membrane of the capsule is folded, if we imagine it to form prolongations which penetrate into all the intervals between the little walls above described. These prolongations adhere to the upper part of the capsule, that is, to the side of it which is nearest the gums, and also to its lateral parietes, but are not adherent to its base, from whence the little gelatinous walls above described arise. Consequently it is easy to understand that there may be a continuous cavity amazingly folded upon itself, extending between all the gelatinous walls (which are descending in the upper teeth, ascending in the lower teeth) and these membranous partitions (ascending in the upper teeth, descending in the lower teeth.)"

"It is in this conceivable cavity that the materials will be deposited to form the teeth, viz. the *bone* or *ivory (dentine)* which will be formed by the gelatinous processes coming from the bottom of the capsule, and the *enamel*, which will be deposited by the membranous septa, and by the general internal surface of the capsule and its prolongations, the base only excepted."

There is, however, according to Cuvier, a very delicate membrane interposed between the ivory and the enamel, which, previous to the deposit of the ivory, immediately infolds the ivory pulp wall, and invests it very closely; but as the ivory pulp transudes the ivory, it is pushed inwards, and separated from this membrane, which then forms a covering common both to the ivory and to the pulp that secretes it.

On the other side the *enamel* is deposited upon the exterior of this membrane by the surface of the prolongations of the internal lamina of the capsule, and by its pressure upon the ivory obliterates the intervening membrane, so that the latter soon becomes imperceptible in the newly formed tooth, or its place is only indicated when a section is made, by a fine greyish line which separates the enamel from the ivory. It is, however, evident that this thin membrane is the only bond of union between the two substances as they become indurated at the bottom of the capsule, for without it they would indubitably separate from each other.

The ivory and the enamel are therefore conjoined by a kind of juxta-position. The former is deposited by layers advancing from without to within, the internal layer being that last formed and also of greatest extent, exactly as in the growth of shells; and as its deposition commences at the most prominent points of the gelatinous, ivory-forming pulp of the tooth, it is at these points that the ivory-forming substance is thickest, and goes on becoming thinner as it recedes from them.

If, therefore, we bring our thoughts to bear upon the epoch when the deposition of ivory commences, it is easy to conceive how there is first formed a little crust of ivory upon each of the prominent points of the indented margins of the ivory pulp, and as new layers are continually within each other, the little crusts are changed into conical caps; when the newly deposited internal layers have descended as far as the bottoms of these indentations, all the caps become united into a single transverse piece; and lastly, when the deposition of ivory has proceeded as far as the bases of the ivory pulps, all the transverse plates will become united into a single crown of a tooth, which would present the same eminences and the same depressions as were conspicuous in the pulp which formed it, if in the mean time other substances had not been in progress of deposition, and partially filled up the intervals between them.

The *enamel* is deposited upon the external surface of the ivory by the internal membrane of the capsule, under the form of little fibres, or rather of minute crystals, all disposed perpendicularly to that surface, so as to form, during the earlier periods of its deposition, a kind of velvet with a very fine pile. When a capsule of a young tooth is opened, the little molecules of the future enamel are in fact easily perceived adhering to the inner surface of the capsule, from which they are easily detached. Some are even seen floating in the fluid that intervenes between the capsule and the germ of the tooth. The opinion of Hunter that the enamel is only a sediment deposited from the fluid interposed between the capsule and the tooth is inexact, inasmuch as he does not attach sufficient importance to the functions of the capsular membrane, from which in reality the molecules of enamel proceed; nevertheless, it is very true that these molecules are originally situated between this membrane and the tooth before they become attached to the latter. But to proceed.

A thick layer of enamel being thus deposited around the ivory forming the crown of the tooth, partially fills up the intervals by which the transverse plates and their indentations were formerly separated. The remainder of these interspaces now remains to be filled up, which is effected by the formation of a third substance, called the *cementum* or *crusta petrosa*. This superadded material, which is very different in its characters from either of the others, is formed by the same membrane and the same surface as formerly produced the enamel. The proof of this is, that the membrane in question always remains external to the *cementum*, in precisely the same relation to it which it previously had to the enamel, and that it continues soft and free as long as the deposition of the cementum leaves room for it. The only change perceptible is in its texture. Whilst it continued to secrete enamel, it was thin and transparent; but when it begins to secrete cementum, it becomes thick, spongy, opaque, and of a reddish colour.

The membranous prolongations of the capsule of the tooth are retracted towards the top and towards the sides of the cavity, in proportion as the cementum which they deposit fills up the spaces between the different lamina of the tooth. The summits even of the laminæ are covered with *cementum* before the tooth begins to be worn. Sometimes, indeed, the same prolongation of the capsule is secreting *cementum* near around the top of a lamina, whilst it is forming *enamel* lower down. From the same cause, the upper portion of the interspaces is already filled up with cementum, while the lower parts remain separate, under which circumstances the lower portion of the capsular prolongation becomes separated from the upper, and only receives its nourishment through its lateral adhesions to the capsule.

The deposit of enamel commences almost at the same time as the formation of the ivory, and the secretion of the *cementum* speedily follows; so that the summit of each lamina has all the three substances belonging to it completely formed long before its base and contiguous laminæ are soldered together by their upper portions, even before their bases are completed. We may likewise add that all these different operations are by no means equally in progress in all points of the tooth at the same time, but they occur much earlier in front than behind; so that the anterior laminæ may be already consolidated by their summits and even by their bases while the bases of the middle ones remain separate, and when the posterior laminæ are not even formed, or only represented by the patches of ivory that are first deposited upon the apices of the pulps.

There was formerly much discussion as to the number of grinding teeth proper to the Elephant, and as early as 1715 the Royal Society of London observed that there is sometimes only one and sometimes two on each side in either jaw, and moreover that the first tooth is longer or shorter in proportion to the second in different individuals. Pallas first explained the real mode of the succession of these teeth, accounting for all these irregularities, and showing that the Elephant has at first only a single tooth on each side, until a second, developing itself, replaces the first, so that during a certain period there are two, until the shedding of the first again leaves only one. Cuvier first announced that this succession and consequent alternate change in the number of the teeth was repeated more than once, because he found the detached germs of a third grinder in the jaw of an Elephant, with two teeth in situ.

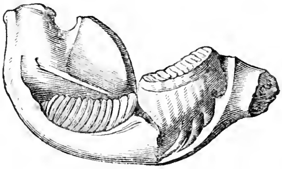
It thus becomes easy to understand how the grinding teeth of the Elephant, notwithstanding the enormous wear to which they are perpetually subject, are kept constantly ready for use, and renovated in front as fast as they are worn away behind. No sooner has the body of the first-formed tooth pierced the gums than it begins to undergo important changes. As the Elephant is herbivorous, its teeth are necessarily worn away by mastication like the teeth of all other herbivorous animals, a circumstance which is indeed necessary in order that the grinding surface may be constantly kept in a condition to bruise vegetable substances. The little indentations on the tops of the laminæ are first worn off, until the wearing down has reached the interior of the tooth, when each denticle of course presents an oval disc of ivory, surrounded by a ring of enamel and enclosed in the cementum, three substances, which, being of very different degrees of hardness, are ground away unequally, so as always to present a rough grinding surface like that of a mill-stone.

The tooth, moreover, by its rhomboidal figure and very oblique position in the jaw, presents its anterior portion above the gums long before the posterior, so that the surface produced by mastication forms an obtuse angle with the plane of the upper surface of the tooth: hence it happens that when the front of the tooth is deeply worn away, the middle laminæ are scarcely used at all, and the hinder ones remain quite intact, presenting the summits of the indentations of their crowns under the form of little round eminences. In the same way the anterior denticles are altogether destroyed before the posterior are very far worn down, a circumstance which explains another phenomenon which is peculiar to the Elephant, viz. that its teeth diminish in length at the same time that they are worn away in depth.

Whilst the exposed part of the tooth is thus worn away, that part of the root which corresponds with the portion ground down is removed by a very different process. When examined under these circumstances, the roots of the anterior denticles have the appearance of being eaten away as by a kind of caries, so that all the front of the tooth is thus removed when the grinding surface has ceased to be efficient, and the tooth, when about to be shed, is reduced to a very small size, however large it might have been originally.

The tooth which is in use is therefore perpetually moving forward in consequence of this process, and making room for that which is in progress of formation in the hinder part of the jaw to succeed it. This latter, in turn, by its development assists in pushing the first forwards, so that it is strictly true that in the Elephant the second set of teeth grows *behind* the milk set, instead of above or below them, as in other animals (*fig.* 479).

Fig. 479.



The tusks of the Elephant are very different in their structure from the molar teeth, consisting of two substances only, the *ivory* and the *enamel*. These tusks grow during the whole life of the animal, and sometimes attain enormous dimensions, measuring eight or nine feet in length, and weighing upwards of two hundred pounds. In the females of the Asiatic Elephant the tusks are very small, but in the African Elephant both sexes have these defences largely developed. These remarkable teeth, which are evidently the representatives of the enormous tusks bestowed on some of the Cetacea, such for example as the Narwal (*Monodon*), are implanted in enormous sockets formed by the intermaxillary bones of the upper jaw. The central portion of each tusk, the *ivory*, which forms by far the greatest portion of the tooth, is secreted by an enormous pulp lodged in a deep cavity which is excavated in its root, from the surface of which it is deposited layer by layer in successive strata. The pulp or nucleus from which the mass of the tooth is thus formed has not the slightest organic connection with the ivory which has been the product of its secretion; not a fibre or vessel, or even the slightest cellulosity passing from one to the other. The tusk is therefore only kept in its socket by the tight embrace of the parts around it, and its direction may be readily changed by gentle and continued pressure, in the same way as dentists succeed in changing he direction of the single-fanged teeth of their patients by the application of wires.

Digestive System.—The digestive apparatus is enormously developed in all the animals belonging to this order, being in this respect not only adapted to the quantity of materials consumed for the support of their unwieldy bodies, but likewise in accordance with the strictly vegetable nature of the aliment upon which they feed, which, compared with animal substances, is necessarily bulky and innutritious. We select a few examples.

The stomach of the Elephant is simple, but in shape it is much more elongated than in the human subject. Its cardiac extremity is prolonged into a pouch of considerable size, the lining membrane of which is gathered into thirteen or fourteen large valvular folds, which, from their great size, seem to form so many broad valves. The muscular tunic of this pouch and around the cardia is remarkably thick, and its contents such as to indicate some analogy between this portion of the stomach and the *abomasus* or fourth stomach of ruminating quadrupeds.

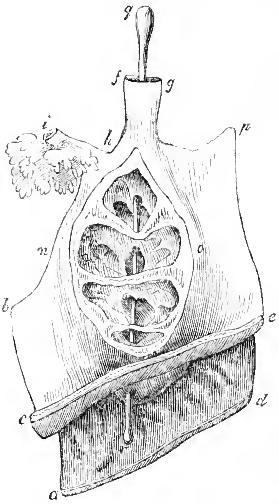
The small intestines are very voluminous, and the colon and cœcum of enormous dimensions, presenting longitudinal tendinous bands and wide pouches as in the human subject. The following table will serve to shew the prodigious extent of the intestinal canal of an Elephant seventeen years of age, and only seven feet and a half in height.

	ft.	in.
Length of the small intestines from the pylorus to the cœcum	38	0
Circumference of ditto	2	0
Length of cœcum	1	6
Circumference of cœcum........	5	0
Circumference of colon.........	6	0
Length of colon and rectum together	20	0
Total length of intestinal canal, exclusive of the cœcum	58	6

The *liver* requires no special notice, but the arrangement of the biliary ducts of the Elephant is very remarkable; and various opinions are recorded by the older anatomists as to whether the Elephant did or did not possess a gall-bladder, most of them denying its existence, while others mistook enlargements of the biliary canals for a true *vesiculum fellis.*

The gall-bladder of the Elephant (*fig.* 480) is, in fact, situated between the coats of the *duodenum* itself, (*b, c, e, p,*) quite at the termination of the biliary duct which comes immediately from the liver. It consists of a great oval pouch divided by transverse valves or septa into four compartments (*n, o*). The fundus and walls of this pouch are studded with glandular granules; the bile enters it at one extremity from the hepatic duct, (*f, g,*) and at the opposite end passes into the interior of the intestine (*a, d, e, c*) through a mamillary projection, situated upwards of two feet from the pylorus, through the orifice of which the point of a probe (*q, r*) is represented as protruding. The arrangement of the pancreatic conduits is likewise remarkable. The pancreas

Fig. 480



consists of a loose arrangement of glandular masses not very closely connected with each other, from which separate ducts are given off, which terminate in a common canal. This latter, however, soon divides into two branches, one of which pours the secretion which it conveys into the upper compartment of the biliary pouch, where it is mixed up with the bile therein contained preparatory to its introduction into the intestine, while the other branch of the pancreatic duct opens into the duodenum itself, about two inches lower down, so that at the orifice bile mixed with the pancreatic secretion enters the duodenum, while from the lower aperture the fluid received is pure pancreatic juice.

The *spleen* of Pachydermatous animals differs in no noticeable respect from that of other quadrupeds. In the Elephant it measures four feet in length, yet even this is thought small when compared with the gigantic size of the animal.

The stomach of the Hippopotamus, or, at all events, of a fœtal Hippopotamus dissected by Daubenton, presents a very remarkable conformation. Externally it appeared to be composed of three parts; the principal portion, extending from the cardiac extremity to the pylorus, was much elongated, resembling more a portion of intestine than an ordinary stomachal receptacle. Besides this central part, extending from the œsophagus to the pyloric valve, were two long appendages like two cœcums, one arising on the right side of the œsophagus and running along the exterior of the stomach throughout almost its entire length, and then folding backwards, the other and shorter cul de sac issuing from the posterior aspect of the cardiac extremity of the stomach and projecting towards the right side. The construction of the interior of this stomach is still more extraordinary than its external appearance, for it is so divided by septa, that food coming into this viscus through the œsophagus may pass by different channels, either into the central portion, which seems properly entitled to the name of stomach, or into either of the great diverticula appended to it. The inferior walls of the central stomach have nine or ten cavities in them, something like those of the Camel and Dromedary. The lining membrane both of the stomach and diverticula is granular and wrinkled except near the pylorus, where the parietes become smooth and folded into numerous plicæ somewhat resembling those of the third stomach of a ruminant, although there is no probability that rumination occurs in the animal under consideration.

In the *hog tribe* the proportionate dimensions of the alimentary canal are very great when compared with the size of the animal's body, the large and small intestines of the Hog or wild Boar measuring together from sixty to sixty-five feet in length, the large intestines alone being in the wild Boar thirteen and in the domestic Hog fifteen feet long. The stomach is capacious, the entrance of the œsophagus being situated nearly in the centre of its lesser curvature, so that the cardiac *cul de sac* is exceedingly large, and is moreover prolonged into a kind of cowl-shaped appendage, which gives it a very peculiar aspect. On opening the stomach the epithelium of the œsophagus is found to be prolonged for some distance into its interior, where it covers a square space of considerable extent, the borders of which are well defined. At the entrance to the pylorus there is a large nipple-shaped projection upwards of an inch in length in the full-grown animal; and moreover, however much the stomach may be distended, there always remains a deep fold crossing it at its upper part, between the œsophagus and the pylorus, and another equally extensive bounding the commencement of the great cardiac *cul de sac*, these folds evidently indicating a relationship with the more complex stomachs met with in ruminating animals, especially as the lining membrane only assumes a villous aspect in the pyloric region of the viscus.

The *liver* consists of four lobes, and there is a distinct gall-bladder, either lodged in a deep fissure, or imbedded in the substance of the middle lobe. The *spleen* is long, flat, and somewhat of a prismatic shape, and the pancreas consists of three portions, which unite near the pylorus.

The *Hyrax Capensis* has a stomach which to a certain extent reminds the anatomist of the complex condition of that viscus met with in many animals nearly related to the Pachydermata. The cardiac extremity is large, and forms a capacious cavity, which is divided by a deep constriction from a second compartment of smaller dimensions, which opens into the pyloric portion of the organ. The whole viscus is moreover so bent upon itself owing to the smallness of the lesser curvature, that the pyloric and cardiac extremities are almost in contact with each other. The cœcum is likewise proportionably of enormous size, being larger than the stomach itself, and from this a spirally folded intestine of no very great calibre runs to a kind of second cœcum of large capacity, which has its commencement prolonged upwards by means of two conical appendages like horns, whence it has been named by Pallas *intestinum bicorne*, and this last, after becoming considerably diminished in size, terminates in the rectum.

Salivary glands.—The salivary organs are very large. In the Hog there are two sublingual glands; one, which is very long and narrow, accompanies the duct of the maxillary gland, and is composed of small lobes of a pale reddish colour; the orifice of its excretory duct is near that of the maxillary. The second sublingual gland is placed in front of the former, and is of a square form; it discharges its secretion through eight or ten short ducts, which pierce the mucous membrane of the mouth. The parotid is large, its duct opening opposite the third molar tooth; and in addition to these there are the molar glands, which form two elongated masses, situated along the alveoli of the superior and inferior molar teeth, and extending forward as far as the canines; these pour their secretion into the mouth through numerous little orifices.

Os hyoides.—The os hyoides in the Elephant has its body or central portion, which resembles a flattened lamina, slightly arched from below upwards, consolidated with the posterior cornua, which divide into two branches as they curve gently backwards and inwards. The anterior cornua articulate with the styloid process of the temporal. In other Pachyderms the general disposition of the hyoid pieces is very similar to the above, but in the Rhinoceros their arrangement approximates what is met with in horned ruminants, the anterior cornua being articulated to the styloid by an intervening osseous piece.

The laryngeal apparatus exhibits nothing extraordinary in its arrangement.

Circulatory and respiratory systems.—The organs of circulation and respiration likewise, in their general arrangement, differ from those of other Mammalia in no important particular. We may, however, notice one or two deviations from the usual type in the origins of the chief venous and arterial trunks.

In the Hyrax the arch of the aorta gives off the arteria innominata, which divides into the right subclavian and the two common carotids, and then a second single trunk, which is the left subclavian.

The Elephant in several points of its economy exhibits remarkable affinities with the Rodentia, in proof of which the correspondence of the structure of its heart with that of some of the Rodents is very striking. Thus the right auricle receives three venæ cavæ, a right and a left superior and an inferior, which latter presents the usual arrangement. Moreover, the Eustachian valve, which is placed between the orifices of the inferior and left superior cavæ, present, in addition to the inferior portion usually met with, the rudiment of a superior division of the valve, extending from the posterior aspect of the orifice of the superior cava. A similar arrangement is met with in the Porcupine and other Rodents.

Urinary organs.—In the young animals the kidneys are separated into several lobes by very deep sulci, but in the adults this lobulated appearance is in a great degree obliterated. In other respects the renal apparatus, ureters, and bladder have nothing peculiar in their structure or disposition.

Generative organs (male).—In the structure of the external generative apparatus of the male Elephant, the principal feature worthy of remark is the existence of two special muscles destined to the retraction of the organ after its erection, an arrangement which is frequently rendered necessary in consequence of its enormous size in that animal, which is stated to be proportionately greater than in any other quadruped. These muscles arise from the anterior part of the os pubis on each side of the penis, and uniting at a little distance from their origin form a common tendon, which runs in a groove along the dorsum of the penis to be inserted into the glans. The action of these muscles will of course be to retract the member into its sheath after erection or after the discharge of urine, which requires a kind of semi-erection, precisely as is the case in the Horse. The other muscles connected with the generative apparatus agree exactly with those met with in the generality of quadrupeds, from which they only differ in size; these are the *acceleratores urinæ* and the *transversales perinæi*.

The *corpora cavernosa*, besides the mesial tendinous septum between them, are traversed by strong secondary septa derived from the external envelope, which is of great thickness in proportion to the enormous size of the organ.

The *verumontanum*, the *prostates*, *Cowper's gland*, the *vasa deferentia*, and the *vesiculæ seminales* occupy their usual positions, and have nothing remarkable in their structure or arrangement.

The testes of the Elephant are not contained in any scrotal pouch or even lodged in the groins, as has been asserted by some authors, who have been deceived by the existence of large glandular masses situated in the inguinal regions; but are deeply situated in the abdomen in close contact with the kidneys, to which they are attached by membranous prolongations resembling little *omenta;* consequently the *vasa deferentia*, which are very large and tortuous, pass immediately to their destination in the commencement of the urethral canal, being closely accompanied by the ureters during the greater part of their course, and lying between those tubes and the rectum.

As another example of the general structure of the male generative organs in Pachydermatous animals, we select those of the Boar. In this creature the glans penis is very long and nearly cylindrical except at the extremity, where it becomes of a prismatic shape ending in a point, which is suddenly bent upon itself. The body of the penis consists of only a single cavernous body, and just above the testes at about four inches from the insertion of the prepuce presents a very singular arrangement, being bent twice upon itself at intervals of about an inch, so as to form at this place a close sigmoid curve; it is flattened for the greater part of its length, but becomes rounded and thinner in the neighbourhood of the glans. The testicles are very large, and the epididymis of each upwards of an inch in length. The vesiculæ seminales are very extensive, occupying their usual position near the termination of the vasa deferentia. The prostates reach from the vesiculæ seminales as far as the ejaculator muscles, lying on each side of the urethra. Each prostate, moreover, is covered externally by a layer of muscular fibre, which is one or two lines in thickness.

In the *American Tapir*, according to Professor Owen, the testes are elongated glands four inches in length, situated externally in a slightly indicated scrotum at the distance of six inches from the anus. The *cremaster* is remarkably powerful, being composed of a strong fasciculus of fibres continued from the lower margin of the internal oblique muscle, of upwards of one inch in breadth. The tunica vaginalis has, as usual, a free communication with the cavity of the abdomen. The penis, which is of great length, is not furnished with levator muscles, but is supported by a quantity of elastic cellular membrane, which extends from the abdominal muscles along the *dorsum penis*.

Generative organs (female).—These present the arrangement usually met with in quadrupeds furnished with a cornuted uterus, the relative size of the uterine apparatus varying in proportion to the fecundity of each genus.

The only description of the female generative organs of the Elephant with which we are acquainted is the following, given by M. Perrault of the parts of one dissected by him in the menagerie of Versailles, many points of which are sufficiently remarkable. That anatomist describes the vulva as being placed almost in the middle of the belly, at a distance of more than two feet from the place where it is usually situated in other animals. The clitoris extended all along this space beneath the vagina and was two inches in diameter, so that, although covered by the skin of the abdomen, it was so apparent as to have been always mistaken for a penis, and the animal was in fact considered to be a male until dissection revealed the mistake.

The vagina extended backward from the vulva to the pubis in a contrary direction to that which it takes in other animals, and at the pubis it formed an angle about the middle of its length, so that the second half ran forward in the usual manner: its lining membrane was very smooth. The edges of the orifice of the womb extended into the vagina for the length of two inches, the neck of the uterus being, as it were, closed by two sigmoid valves, so disposed, according to Mons. Perrault, to prevent the urine from entering the womb, because the urethra opens into the vagina so near the os tincæ that the urine flows more readily towards the womb than towards the vulva, the angular bend in the vagina forming an obstacle to its passage in the latter direction.

The body of the uterus was oval, and measured a foot and a half in length by ten inches in breadth. The cornua uteri were each two feet eight inches in length, and four inches and a half in circumference: their openings into the womb were surrounded by a prolongation of their lining membrane, hanging into the uterus like a fringe or valve, so that any thing which had passed from the cornua into the uterus could not return again from the uterus into the cornua, which latter were united to each other for about a foot from the body of the uterus. The Fallopian tubes were only two inches in length, and the ovaria of very small size.

In the *Sow* the vulva occupies its usual situation between the pubic symphysis and the anus. The glans clitoridis is bent upon itself and terminates in a point resembling the penis of the Boar in miniature. The walls of the vagina are much plicated for an extent of two or three inches from the orifice of the womb, and in this part its canal is considerably wider than near the entrance of the vulva. The *os tincæ* is only indicated by a slightly elevated margin. The *cornua uteri* are of great length, being convoluted much after the manner of the small intestines. The fimbriated extremities of the Fallopian tubes are only connected at one point with the ovaria, the rest being loose and floating. The ov ries in the common Sow are of very irregular contour, the Graafian vesicles (as big as peas) standing prominently out from their surface.

In the Elephant the mammæ are pectoral and only two in number, one situated on each side of the breast.

The Rhinoceros, the Tapir, and the Hippopotamus have likewise only two mammæ, but they are placed beneath the belly.

In the Hog there are generally ten nipples both in the male and female; these are situated beneath the belly, five on each side, but sometimes there are five on one side and six on the other, and occasionally six on both sides.

Of the Nervous System. Brain.—The brain in the Pachydermata is largely developed, and the convolutions upon its surface comparatively small, though very numerous and separated from each other by deep sulci. In the Elephant the absolute size of the organ exceeds that of man, but is very small in proportion to the bulk of the animal, especially when we take into the account the great size and intellectual aspect of the head. In an Elephant dissected by the Parisian Academicians, which was seven feet and a half high from the ground to the top of the back, and eight feet and a half in length from the forehead to the tail, the brain and cerebellum together weighed nine pounds. The convolutions upon the surface of the cerebrum were well marked, and the proportionate size of the cerebellum is described to have been enormous; the brains of the Rhinoceros and Tapir are equally large in proportion, but the relative size of the cerebrum, especially of its anterior and superior regions, when compared with the rest of the brain, is much less. The hippocampus and corpus striatum are well developed, and the lateral ventricles are continued forwards into the dilated olfactory bulbs. The cerebellum is very large and expanded transversely, its surface being still further increased by numerous and complex anfractuosities. The pons Varolii corresponds in size with the developement of the lateral lobes of the cerebellum, and the corpora olivaria are remarkably prominent. In other respects the brain of the animals included in this order presents no peculiarities worthy of special notice. The nerves take their rise in the usual manner, and have the same distribution as in other Mammalia. In those races, however, which have the nose largely developed, the fifth pair is remarkable for its great size, and in the Proboscidian species these nerves are of enormous dimensions.

The dura mater is very thick, proportioned rather to the size of the skull and of the entire animal than to that of the brain itself; and its two fibrous layers are found in the larger species to be separated by a quantity of cellular substance in which the vessels ramify.

The spinal chord presents no peculiarity worthy of being distinctly alluded to.

Of the Special Senses. Touch.—In animals whose limbs seem to be converted into mere pillars of support, and whose hoof-cased feet are totally destitute of all power of prehension, it would hardly have been expected that any nicety of appreciating tactile impressions should exist in the situations usually appropriated to this sense, more especially when we take into the account the thickness and density of the integument with which they are clothed.

The nasal apparatus, however, in all the Pachydermata, is richly endowed with nerves of sensation, and obviously forms a very perfect organ of touch. It is moreover in some measure converted into an instrument of prehension, or is employed for digging the soil in search of food, as well as for the usual offices assigned to it; in fact it is in this group of quadrupeds alone that the nasal cartilages and the muscles of the nose assume their full developement, and accordingly will merit special notice in this place.

In the *Hog* the cartilages of the nose form a complete tube, which is a continuation of the bony nostrils, and near the end of the snout, in the vicinity of the *septum narium*, the extremity of the cartilages becomes ossified, and in the dried skull seems to form an additional bone (*fig.* 481). Four strong pairs of muscles, derived from the bones of the face, confer upon the organ considerable power of motion, and render it very efficient in tearing up the earth. Of these muscles the first pair arises in front of the orbit from the lacrymal bone, and terminates in a strong tendon which spreads out upon the upper aspect of the nasal cartilages. Two other pairs situated beneath the preceding are derived from the superior maxillary bone in front of the zygomatic process: these muscles are partially united, but their tendons run separately to be inserted, one into the side, the other into the base of the snout. The fourth pair is comparatively of small size, arising from the nasal bone, and running obliquely beneath the tendons of the two last, terminates near their insertion. The snout and all the above longitudinal muscles are moreover enclosed by a layer of annular fibres, which are a continuation of the *orbicularis oris*, so that considerable mobility in any required direction is thus amply provided for.

In the construction of the snout of the Tapir the arrangement of the nasal cartilages and muscles of the nose is still more elaborate, forming a rudimentary proboscis which is only surpassed in complexity by the trunk of the Elephant, the only existing type of the true Proboscidian Mammalia: in fact it is constructed upon the same principles, the great difference consisting in the diminutive size of the organ in the Tapir when contrasted with the prodigious dimensions of the corresponding parts in the Elephant's proboscis. The nose of the Tapir is composed of two membranous tubes, amply provided with mucous lacunæ, and enclosed in a fleshy mass surrounded by the skin, which consists of longitudinal muscles that take their origin beneath the lower margin of the orbit, and of fasciculi of transverse fibres passing between the skin and the external surface of the membranous nasal tubes. There is a pair of muscles in every way similar to the *elevators* of the upper lip of the *Horse*, derived from the precincts of the orbit, and uniting into a common tendon to be inserted into the upper aspect of the nose, a pair of depressors arising from the intermaxillary bones, and also a slip derived from the *occipito-frontalis*, which is implanted by the intervention of a tendon into the base of the proboscis.

The proboscis of the Elephant, the only existing example of a completely developed nasal apparatus, forms an elongated cone of four or five feet in length, and gradually tapering from the root towards the point, which is terminated by a kind of thumb-like appendage which is endowed with exquisite sensibility, so as to be useful in picking up the smallest objects. Internally the Elephant's trunk is perforated by a double tube, formed by a strong tendinous membrane, through which innumerable mucous crypts pour fluid abundantly into the nose. The membranous tubes are continued upwards as far as the bony nostrils, but, a little before their junction with the latter, they form two curves, the nasal passages being closed at this point by a cartilaginous elastic valve, which may be opened at the will of the animal, but closes by its own elasticity when the muscles which open it cease to act.

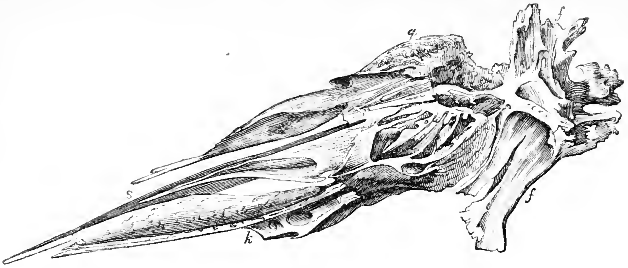
All the interval between the membranous tubes which follow the axis of the proboscis, and the skin by which it is invested externally, is filled up with a thick layer of muscular substance composed of two sets of fibres. Of these one set passes from the exterior of the membranous tubes to a strong tendinous membrane situated immediately beneath the skin in such a way that on making a transverse section of the trunk, these muscles represent the radii of a circle: their action will be, of course, to approximate the membranous tubes and the external integument of the trunk, and thus by compressing the intervening space, their contraction will have the effect of elongating the whole proboscis, without at the same time diminishing the calibre of the membranous tubes, as would have been the case had annular fibres been employed instead of this remarkable arrangement.

The other muscles of the proboscis are disposed longitudinally, and form a multitude of fasciculi, disposed in short curves in such a manner that the two extremities of each fasciculus are implanted into the membranous tubes, while the convexity of the arch is adherent to the external tendinous membrane. These fasciculi surround the whole trunk, and extend along its entire length; their effect being to shorten it from end to end or in any part the animal may please. It is evident that by these partial elongations or shortenings of one side or the other, the Elephant can bend its trunk in any direction with the utmost ease, and make use of it as efficiently as a hand in the performance of many important offices. In addition to the above account of the anatomy of this remarkable apparatus given by the Parisian Academicians, Cuvier ascertained that all the longitudinal fasciculi which enter into the composition of the trunk are derivations from four great muscles, which, though almost blended together in the trunk itself, are distinct enough near their commencements. Of these the two anterior arise from the whole breadth of the frontal bone above the ossa nasi, while the two lateral muscles take their origins from the superior maxillary bones beneath and in front of the orbit. The posterior or inferior aspect of the Elephant's proboscis is covered with fibres, which seem to be continuations of the *orbicularis oris*, and which run obliquely downwards and inwards so as to meet their fellows from the opposite side at an acute angle. With such a structure it is evident that the nasal prolongation of the Proboscidian Pachyderms is able to move in every needful direction, and perform all the duties of a lithe and flexible arm, strong enough to tear the branches from the trees, and sufficiently manageable to be available for the most delicate manipulations.

The instruments of the senses present few peculiarities.

In connection with the organs of smell we may conveniently mention the sinuses which communicate with the nasal cavities, which in many Pachydermata are extremely developed. The *frontal sinuses* of the Elephant are of enormous extent, reaching throughout all the thickness of the frontal, of the parietal, of the temporal, and even extending into the condyles of the occiput. The whole of this extensive cavity is divided into cells by numerous imperfect septa, irregularly disposed. In the Hog tribes they are equally extensive, but far more shallow; they reach as far back as the occiput,

Fig. 481.



Sphenoidal and vomerine plates of a young Boar (Sus Scrofa).

and are divided into communicating cells by longitudinal or slightly oblique lamellæ of bone. In the *Babiroussa* there are four rows of such cells, and in the common *Hog* seven or eight. In the Hippopotamus and Rhinoceros the frontal sinuses can scarcely be said to exist.

The *maxillary sinuses* are very large in the Elephant, and are divided into numerous intercommunicating cells which open into the side of the nose by a wide orifice. In the Hog tribe these sinuses do not exist, but in their stead their is a cavity in the malar bone, which in the Ethiopic Boar is very large. A similar cavity of smaller size exists in the Hippopotamus.

The *sphenoidal sinuses* are very small except in the Elephant, in which, like the preceding, they are of unusual dimensions, extending even into the pterygoid processes; but they are not divided into cells as are the other sinuses of this creature.

Eye.—The optic apparatus requires but a few passing observations.

The external boundary of the orbit is completed by a strong ligamentous margin.

The third eyelid is very largely developed in the Elephant, and can be drawn over the eyeball to a considerable distance towards the outer angle of the eye. It is provided in this animal with two special muscles which do not exist in other quadrupeds. One of these, which seems to draw the nictitating membrane over the eye-ball, arises from the lower margin of the orbit, towards the outer canthus; while the other, which is the antagonist of the former, draws it back again towards the inner angle.

The Harderian gland is of very great size, and opens by a capacious duct upon the inner surface and close to the base of the third eyelid; in some species, however, as in the Elephant, numerous small accessory glands are met with, the excretory orifices of which terminate near the margin of the nictitating membrane. The nictitating membrane itself is very large, and sometimes contains a flat, thin, and slightly curved cartilage. Moreover, in the Elephant especially this membrane really deserves to be considered as a proper eyelid, being moved by a distinct muscle, the *nictitator*, the fibres of which pass in a regular curve over the base of the membrane, but afterwards deviate from the curve and form an angle to include the extremity of the nictitating cartilage, which consequently moves in the diagonal of the contracting forces so as to be drawn outwards over the front of the eyeball.

Ligamentum nuchæ. — The ligamentum nuchæ is of enormous strength, more especially in the larger Pachydermata, such as the Elephant and Rhinoceros, where the ponderous head necessarily requires unusual support.

In the American Tapir this ligament consists of three strong portions, two of which pass in a parallel direction from the elongated spinous process of the first dorsal vertebræ, to be inserted together into the superior and posterior angle of the central ridge of the cranium supporting the whole length of the elevated crest and mane; the third portion runs beneath the other two, to be inserted into the most elevated part of the elongated spinous process of the *vertebra dentata*.

PACINIAN BODIES, so named after Filippo Pacini, professor of anatomy at Pisa, who discovered them in 1830, and subsequently published two memoirs upon them. They are peculiar minute organs appended to the nervous system, and present an arrangement altogether novel and full of interest, though as yet their use is entirely unknown.

The essential structure of these corpuscles appears to be the following. A single tubular or white nervous fibre leaves the fasciculus of which it forms a part, and carrying with it a process of the fibrous neurilemma, advances right into the centre of a series of concentric ovoidal capsules of fibrous membrane, through a channel which perforates them all, and which has its proper wall, to which every capsule is attached. All the capsules, except from five to twenty of the inner ones, have spaces between them containing a clear watery fluid. These spaces do not communicate with one another or with the channel in which the nerve runs. Each one is distended by its own fluid, and in the natural state is more or less tense, offering

Pacinian corpuscle, from the mesentery of a cat; intended to shew the general construction of these bodies. The stalk and body, the outer and the inner system of capsules, with the central cavity, are seen.

a. Arterial twig, ending in capillaries, which form loops in some of the intercapsular spaces, and one penetrates to the central capsule. *b.* The fibrous tissue of the stalk, prolonged from the neurilemma. *n.* Nerve-tube advancing to the central capsule, there losing its white substance, and stretching along the axis to the opposite end, where it is fixed by a tubercular enlargement.—*From Todd and Bowman.*

resistance to external pressure. The innermost capsule of all is an elongated nearly cylindrical cavity, somewhat larger at the further end, and always contains a clear fluid, which distends it and prevents its sides from falling together. The nerve-tube has the ordinary double dark contour as well as every other character of those found in the ordinary cerebro-spinal fibres until its entry into the central capsule. At that point it becomes less bulky, somewhat flattened (so that its section is oval instead of round), and in particular much paler. The dark border which has distinguished it hitherto now disappears, and if it were not for the transparency of the contents of the capsules its further course would be untraceable. It is, however, when fresh, and with a good light, distinctly seen to proceed along the very axis of the central capsule from one end to the other, and finally to be implanted by more or less of a swelling (*fig.* 483) into the further extremity

Fig. 483.

of this central compartment. The originally dark border of the nerve-tube does not cease with absolute abruptness, but the two lines of the border coalesce in a somewhat sloping manner, and the pale continuation has merely a single bounding line, and that so exceedingly thin as not to allow of being described as an investment distinct from the rest of the fibre. This line, as Henle and Kölliker have remarked, is more evident when the edge of the flattened fibre is towards the observer than when the flat surface is upwards, in which latter position it is sometimes altogether absent.

Such is the general plan of the structure of these bodies. Their usual length is from 1-20th to 1-10th of an inch, and their stalk is often 1-10th of an inch long. Though usually oval, they are often more or less elongated and bent on themselves. Sometimes the internal capsules only are bent, while the outermost are simply oval. In the human subject they are found in large numbers, detached or in clusters, in the subcutaneous areolar and adipose tissues of the palm and sole, in connection with the cutaneous nerves, as well as more sparingly in the same connection at other parts of the extremities. A few are also met with in the sympathetic plexuses; and in the cat in particular they are usually so abundant in the mesentery and omentum, as instantly to arrest the eye when these parts are spread before it. They are here indeed most favourably situated for examination. They are included merely between the duplicature of the transparent peritoneum, can be obtained in great numbers perfectly fresh, and admit of being inspected without the addition of any water or other medium.

Fig. 484.

One of the nerves of the palm with the corpuscles appended, and of natural size. After Henle and Kölliker.

To the naked eye they here present a beautiful semi-transparent pearly lustre, with a whitish opaline streak along the axis, resulting from the greater proximity and density of the series of internal capsules. In some animals of this species they have appeared to me almost wanting. It is remarkable that in no instance have they been detected in connection with nerves purely motor, nor, it is affirmed, on the fifth nerve or the glosso-pharyngeal.

The *stalk* consists, as has been said, of a production of the neurilemma enclosing a single nerve-tube. It sometimes happens that there are two nerve-tubes, but then there are two corpuscles on the single stem, either in close apposition, or actually enveloped by a few capsules common to both. The nerve-tube in the stalk is undulating, and being accompanied by white fibrous tissue is easily distinguished by its peculiar structure. The artery and vein supplying the corpuscle are also included in the stalk.

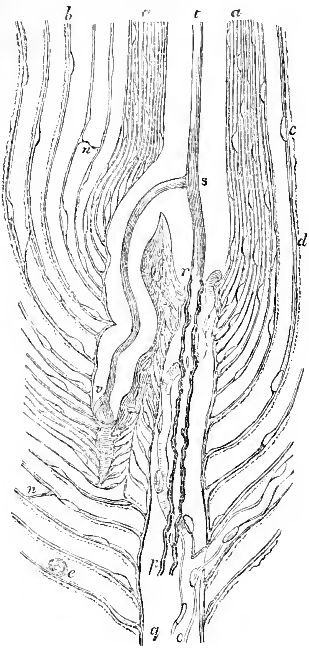
The *channel* which the stalk occupies in its passage through the capsules, is conical and comes to a termination at the proximal end of the innermost capsule. It is furnished with a membranous wall, with which the fibrous tissue of the stalk is united on the inside and the several capsules on the other, and by this means the intercapsular spaces are preserved closed, and their fluid retained. This wall usually presents irregularities of outline, and often a cellular appearance, where the capsules, and especially the inner ones, join it. It is perforated by the minute vessels as they enter some of the intercapsular spaces (*fig.* 482).

The *capsules* themselves are inelastic membranes, analogous probably to the white fibrous tissue, and furnished with clear transparent nuclei that project chiefly on the inner surface. This is true of all the capsules, but in the outer system or those thicker and stronger ones between which fluid intervenes, there is evidence of a double wall; for in addition to the clear double line which distinguishes all, these present also on their outside, when seen edgeways, a series of dots, which indicate a system of transverse or circular fibres, and in fact the corpuscle, when brought into focus, shows no other fibrillation than this transverse one. Almost all appearance of a fibrous texture is removed by acetic acid, so that the yellow or elastic fibre does not appear to form any portion of the capsular membranes. The outermost capsule, indeed, is invested with both the elastic and the inelastic fibres, but these are to be regarded as belonging rather to the areolar tissue in which the corpuscles are imbedded, than to these organs themselves. The capsules are united together by the wall of the channel of the stalk. They are also joined here and there by partial membranous septa passing directly or obliquely across the intercapsular spaces, and which seem to be of the same nature as the capsules themselves. Pacini describes further a union of the capsules at the distal end in the axis of the corpuscle, which is denied by Henle and Kölliker to exist. I have had, however, unequivocal evidence of its existence, especially between the inner capsules, when they have been artificially distended by water, although it often appears to cease towards the surface. When the end of the capsules is bent on itself, the line of this intercapsular union is less easy to trace.

The small *artery* supplying the corpuscle subdivides in the channel of the stalk into its three, four, or more capillaries, which pierce the wall and enter the intercapsular spaces. After advancing in these for a variable distance they form loops, and return by a similar route to the small corresponding vein. In the larger corpuscles I have seen a little bunch of vessels formed near the further end by some of these capillaries. In most cases a single capillary accompanies the nerve-tube as far as the central capsule, and then passes for some way upon its wall, sometimes in a spiral direction. If a perfectly fresh corpuscle from the mesentery of a cat be examined before the blood has drained off, the addition of a little water will occasionally induce a rapid movement of the contents of these minute vessels under the eye of the observer, by gaining entrance to their interior; and few objects are more beautiful than the miniature circulation thus artificially brought about for a brief period. The capillaries have their proper walls, furnished with nuclei.

The *central cavity*, in size, and particularly in shape, is liable to much variety. It has been already stated to be not unfrequently bent upon itself towards the further end; sometimes it is bifurcated, or, more correctly, branched, the offset then passing in a recurrent course either from the commencement or the middle part of its length. In this case the branch is surrounded by the same series of internal close capsules, and external ones separated by fluid, which encircle the principal cavity, only accommodated to the irregular conformation. However the central cavity is modified, it always retains its transparent character, and on its inner

Fig. 485.



Portion of a Pacinian corpuscle, from the mesentery of a cat.

a a, the internal capsules; *b b*, capsules of the external system, with intervening fluid. Corpuscles, as at *c*, are seen in all the capsules. The outer capsules show a double layer, *d*; *e*, occasional form of corpuscle in the intercapsular spaces; *n n*, connecting membrane between two capsules; *o*, capillary vessel containing corpuscles or nuclei in its wall, and lying with *p*, a tubular nerve-fibre in *q*, the channel of the stalk, the fibrous tissue surrounding them not being represented. The vessel divides into two branches, one of which perforates the wall of the channel of the stalk and enters an intercapsular space, and the other advances as far as the central capsule. The nerve has the double contour as far as *r*, where it enters the central capsule; from that point it is pale and faint. This specimen represents an offset of the central cavity, and of the pale nerve at *s*. The stem continues its course, *t*, towards the further end of the central cavity, while the offset follows the curved axis of the subordinate cavity as far as *v*, where it ends in a bulb by which it is fixed. Several of the capsules are united together at *x*. Magnified about 300 diameters.

surface exhibits very faintly marked elongated nuclei, which most probably belong to the wall of the inner capsule.

There is little to add to the description of the *nerve-tube* already given. It is faintly granular in texture, and occasionally regains, at one or more points of its course within the central capsule, the dark contour which it had lost on entering it. This is particularly the case when it follows a bend of the cavity, and certainly seems to indicate the presence there of a material elsewhere deficient. It is rare, however, to see this re-assumption of the dark border in any very well-marked degree. The mode of attachment of the end of the nerve-fibre varies, being generally by a single tubercle or conical swelling, sometimes by two, and sometimes even by three such. Whatever the number of branches, however, their aggregate thickness is about the same as that of the simple fibre from which they spring. Where the central cavity exhibits the offsets above-mentioned the pale nerve-fibre is also invariably branched, its subordinate branch always traversing the axis of the subordinate cavity, and being regularly fixed at its extremity. It is interesting to observe how accurately the nerve-fibre preserves its place in the axis of the central cavity, however abruptly that may be bent or branched, a fact which might be supposed to indicate some degree of viscidity in the clear substance through which it runs.

Respecting the *function* or *use* of the Pacinian corpuscles no satisfactory account has yet been given, nor even a plausible explanation offered. Their presence in so great abundance on the nerves of the palm and sole, and their absence from motor nerves, suggests the obvious enquiry, whether they may not be connected in some way with the sense of touch, or at least with the function of sensation, to which the fact of their concentration in such numbers in the splanchnic nerves of some animals as obviously answers in the negative. Undoubtedly, however, we may anticipate much from a more extended research into their connections with the several parts of the nervous system in man and animals, than the very recent date of their disvovery has yet allowed. The speculation that they may be concerned in the phenomena of what is called animal magnetism is not to be passed over with contempt, if only because it has been hazarded by their distinguished discoverer, Pacini, who, in common with many other unprejudiced and not incapable observers, is inclined to believe in the reality of some of the less marvellous effects which popularly pass under that title, such, in particular, as the mesmeric somnolence and catalepsy. Yet so vague an hypothesis, perhaps, barely deserves to be placed in juxtaposition with the descriptive anatomy of the corpuscles.

It will be more to the purpose to institute a brief *comparison between these bodies and the electrical organs of the torpedo*, a description of which will be found under the head of Animal Electricity. Since that article was written, however, further researches, and especially those of Savi,* have added some points of importance which it will first be necessary to no-

* Savi, Etudes Anatomiques sur le système nerveux et sur l'organe électrique de la Torpille. Vide Matteucci, Traité des phénomènes electro-physiologiques. Paris, 1844.

tice. The prisms of the electrical organ, as Hunter described, are divided by very numerous horizontal diaphragms into spaces containing a thin fluid, and on these diaphragms the nerves and vessels of the organ are ultimately distributed in great abundance. Each of these superposed diaphragms consists of a layer, possibly double, in and not upon which the nerves ramify. The nerves of the electrical organ have never any ganglia formed upon them. Their tubules always have the double contour which marks the presence of the white substance of Schwann. The ramifications penetrate between the prisms, and each diaphragm receives tubular fibres at several points of its circumference, though Savi is doubtful whether these are derived from two or more tubules of the branch supplying them. In the diaphragm, however, they are uniformly spread out in a network with five or six-sided meshes, the sides of which are everywhere formed by a single tubule with double contour of the same diameter and structure as the tubules of the trunk of the nerve. If this network is supplied from several different tubules, these tubules must be described as inosculating to form it; if from a single tubule, this must be regarded as again and again branching dichotomously, and the branches repeatedly anastomosing. Whichever be correct, the existence of a true network of ultimate nerve-tubes with double contour is certainly a fact of much importance, and hitherto unique; and it appears to be satisfactorily established by the repeated accurate observations of Savi.

The series of superposed membranes in the prisms of the electrical organs may have an analogy with the concentric capsules of the Pacinian bodies. Their separation by intervening fluid is another point of resemblance. But in their relation to the nerves they are quite unlike. In the one, each membrane has a plane network of nervous tubules in its substance; in the other a single nerve-fibre is placed in the axis of a series of concentric membranes. The condition of the nerves is also different. In the one the white substance of Schwann everywhere invests the nerve; in the other it is suddenly lost on entering the central capsule. The branching of the nerve-tubes in the electrical organ has a correspondence with the frequent tendency of the pale fibre of the Pacinian corpuscle to divide into two or more parts. On the whole, perhaps, the comparison may suffice to raise the question, whether the Pacinian corpuscles may not be organs designed to generate some kind of force, which the nervous communication with the centres may serve to connect either with volition or some emotional impulse or feeling.*

There is another set of organs, however, in the electric torpedo, the discovery of which we owe to Savi, and which bear a closer resemblance to the Pacinian corpuscles than the electric organs themselves. These are what he terms the *follicular nervous apparatus*, and which I shall briefly describe nearly in his own words.*

" This apparatus is found bordering the anterior part of the mouth and nostrils, and extends over the surface of the anterior part of the electrical organs, and over the front half of their outer edge, where it rests upon the cartilage and aponeurotic coverings of the fin. Some parts of the apparatus are found on the back, but the greater portion on the ventral surface of the animal. It consists of extensive linear series of follicles, or closed membranous cells with double walls filled with a gelatinous fluid, and enclosing a small amorphous granular mass, which nearly resembles the amorphous grey matter of the cerebral hemispheres. A nervous branch gives some fibres to this granular mass, while other similar fibres united into bundles pass out of the follicle, penetrate the grey mass of the adjoining follicle, and mingle with its nerve.

" The nerves distributed to this apparatus come exclusively from the fifth pair, and more particularly from the branches springing from the anterior portion of the root. Each follicle (*fig.* 486) is of a spheroidal form, slightly compressed on the side which adheres to the neighbouring follicle, and its diameter is about $\frac{1}{12}$th of an inch. I have found these dimensions the same in animals of very different size. These follicles are never free or floating in the gelatinous fluid so abundant in these fishes: on the contrary, they are always firmly fixed, as if with a special view to their security, for they are planted on unyielding aponeurotic expansions, like that of the muzzle, or else on fibrous bands extending along the fin, and having no other use. When the gelatinous fluid which envelopes these follicles is examined under the microscope, it is seen to contain numerous fibres passing in various directions, and fixed to the surface of the follicles.

" Each follicle is formed of two membranes (*f* and *g*) which adhere together on the side towards the fibrous band which supports the organ, whilst on the opposite side they are separated by about a third of the vertical diameter of the follicle. These organs may be easily examined by a very slight magnifying power, it being only necessary in the first place to remove the investing gelatinous substance, and then to subject them to moderate compression for the display of their interior. In a follicle thus compressed, we observe first the cut portion of the tendinous band *cc*, then the outer membrane enclosing the other, in which is the rounded granular mass *e* already mentioned. This latter seems to rest upon the lower wall of the internal membrane. The external membrane adheres by its lower border to the fibrous band beneath it in such a way, that between this external wall of the follicle and the internal is left a space, in which the nervous ramification *d* advances and adheres to the rounded mass of granular substance.

" In the follicles of the longitudinal series of the fin, of which we here speak, the nervous

* Henle and Kölliker endeavoured to elicit evidence of an electric discharge from the Pacinian bodies of the cat's abdomen, but without success.

* Op. cit. p. 332.

(Fig. 486.)

a, branch of fifth pair of nerves; *b*, twigs going to the organ and passing through *cc*, the fibrous band; *d*, the nerve as it lies on *e*, the granular mass; *f* and *g*, the inner and the outer capsules containing fluid; *k* anastomosing filament from the preceding follicle; *l*, anastomosing filament to the succeeding follicle. Much magnified and slightly compressed. *From Savi.*

twig is derived from the fifth pair and passes first through a slit in the tendinous band. After passing this aperture it bends underneath the granular mass, and again emerges at the base of the follicle, but at the opposite side from that at which it entered. It is remarkable that the nerve is much thinner at its exit, and reduced to an exceedingly delicate filament (*l*), which proceeds along the tendinous band to the next follicle, penetrating its wall and joining its nerve at the point of its flexion under the granular mass (*k*).

" On examining under the microscope the rounded granular mass, made flat by the compressor, and after the removal of the membranes of the follicle, we see the nerve running lengthwise over it from end to end, the anastomosing branch coming from the preceding follicle (*k*) and the very delicate filament which proceeds to that next in order (*l*). We further remark that the nerve of the follicle, in its course along the granular mass, gives off a great number of elementary fibres, which disseminate themselves through the mass and thus reduce the nerve to so small a size. Sometimes I have fancied that these fibres formed loops and returned; but I have never obtained a clear view of their termination. I am no less doubtful regarding the course of the elementary fibres of the anastomosing branch coming from the preceding follicle. Sometimes I have seen these fibres return towards the slit in the tendinous band and rejoin the nerve in order to regain the centre. In other cases I have seen these fibres pursue their primitive direction, and pass on with the rest towards the opposite end of the granular mass. Hence I imagine that the fibres of the anastomosing bundle do not all follow the same course, and that while some advance into the granular mass, others turn back towards the centre through the slit in the fibrous band." " It occasionally happens that two nervous twigs pass from the main branch to the same follicle. When this happens, there are always two distinct granular masses." M. Savi then describes accurately the arrangement of the several series of these follicles in the torpedos which he examined, an account of which is not necessary for our present purpose. In one example he found that the follicles amounted in all to two hundred and fourteen.

We cannot adduce these remarkable and peculiar structures as at present throwing any light on the function of the Pacinian corpuscles, since we must confess with M. Savi that as yet we are entirely ignorant both of their real nature and use. Nevertheless the resemblance is such as, it is hoped, will warrant the introduction of the preceding account, which is new in this country, and very interesting in itself. It is unnecessary to recapitulate the several points of similarity and difference, which, after the detailed description of each now offered, may be readily apprehended by the reader himself.

It only remains that we should direct attention to the very admirable memoir of Henle and Kölliker on this subject. They corroborated the principal results of Pacini, and added many most valuable observations which the use of higher powers of the microscope and perhaps greater experience in research had enabled them to make. These observations M. Pacini has recently informed me he has himself almost entirely confirmed. An excellent abstract of their labours appeared in the British and Foreign Medical Review for January, 1845, and in the following April Dr. Todd and myself gave an account of these structures, drawn up from original observations and containing some new results, though on the whole confirmatory of those previously published. See the Physiological Anatomy and Physiology of Man, vol. i. p. 395.

It is right to add that MM. A. G. Andral, Camus, and Lacroix, met with these bodies in 1833, and that they were noticed subsequently by Cruveilhier and Blandin in their respective works on descriptive anatomy, bnt without any real light being thrown on their nature or internal structure.

(William Bowman.)

PAR VAGUM NERVE. (Human Anatomy.) — (*Nervus Vagus; Pneumogastric*; part of the *sixth pair* of nerves of the older anatomists; *one* of the three divisions of the *eighth pair* in the classification of Willis; the *ninth pair* of Andersch; the *tenth pair* of Sömmerring; the *moyen sympathique* of Winslow.) The par vagum, like the other cerebro-spinal nerves, consists of two nerves exactly similar at their origin, and placed on different sides of the mesial line of the body. It has a very long course,—passing down the neck, and through the thorax to the upper part of the abdomen,—is distributed upon numerous and dissimilar organs, and anastomoses very freely and extensively with the *sympathetic* and various *cerebro-spinal* nerves. It is the chief nerve of the lungs and stomach, and hence its appellation of pneumo-gastric.

The *nervus vagus* arises by several filaments, generally from six to ten, from the restiform body of the medulla oblongata, parallel to and a little posterior to the groove between the olivary and restiform bodies, and from a line to a line and a half distant from the posterior edge of the olivary body. The arciform band of superficial filaments passing between the anterior pyramidal and restiform bodies cross among the lower filaments of this nerve. The filaments of the vagus are attached to the restiform body in a vertical, straight, and thin band of from three to four lines in length, the upper end of which is separated from the lower edge of the glosso-pharyngeal nerve by a few small bloodvessels only. The upper half of these filaments of the vagus are at their origin closely approximated, so that the lower edge of the one above is in contact with the upper edge of the one below, while the lower filaments, especially the two last, are considerably more distant from each other. The lowest filament is placed only a little above and in the same line with the uppermost filament of the spinal accessory, and it is frequently difficult to determine where the filaments of the accessory begin, and where those of the vagus end. From this origin each *vagus* proceeds forwards and outwards between the lower surface of the lateral lobe of the cerebellum and that portion of the dura mater covering the basilar process of the occipital bone, to reach the foramen lacerum posterius, through the anterior part of which opening it escapes from the interior of the cranium. In this part of its course it frequently anastomoses with the glosso-pharyngeal, and its filaments become more subdivided, but at the same time more closely aggregated, so that it is thicker and narrower. On reaching the foramen lacerum posterius it enters a sheath or canal in the dura mater, anterior and a little internal to the commencement of the internal jugular vein, immediately anterior to the spinal accessory nerve, and posterior to the glosso-pharyngeal. As these three nerves enter the foramen lacerum, they perforate the dura mater, the glosso-pharyngeal by a separate and distinct opening, the nervus vagus and spinal accessory by an opening common to both. Sometimes there is a small bridle of dura mater, at other times only a fold of the arachnoid separating the vagus and accessory at this part. At the lower part of the foramen lacerum the *spinal accessory* is closely applied to the posterior surface of the vagus. The dura mater is prolonged downwards into the foramen lacerum upon these three nerves in the form of two sheaths, one sheath surrounding the glosso-pharyngeal, and the other the vagus and accessory. From the proximity of these three nerves, as they pass through the foramen lacerum posterius, and from their intimate connection in some parts of their course and subsequent distribution, they were long considered to form only a single nerve.

As the vagus lies in the foramen lacerum it presents a greyish oblong swelling, resembling the ganglion on the posterior root of a spinal nerve *(ganglion primum nervi vagi of Wutzer, ganglion radicis n. v. of Bendz, ganglion superius n. v., ganglion jugulare n. v.)* This ganglionic enlargement begins immediately after the nerve has entered the foramen lacerum, so that its upper edge may be sometimes seen from within the cranium; it is of an oval form, and it extends along the course of the nerve from a line and a half to two lines.* Mr. James Spence† has pointed out that a small filament belonging to the lower part of the vagus passes over the posterior surface of this ganglion without entering it, and joins itself to the superior filaments of the spinal accessory.‡ This fact, as we shall afterwards find, has a direct bearing upon the physiology of the nerve. A communicating filament passes between the ganglion superius of the vagus and the superior cervical ganglion of the sympathetic, another between it and the ganglion petrosum of the glosso-pharyngeal, (vide article Glosso-Pharyngeal,) and one or more between it and the spinal accessory.§ From the

* Arnold (Der Kopftheil des vegetativen Nervensystems beim Menschen. S. 107) describes this ganglion as varying little in size, and as measuring a line and a half to a line and three quarters in breadth, a line to a line and a half in length, and three quarters to one line in thickness. He found a difference of about two lines between the measurement of the circumference of the ganglion and the trunk of the nerve immediately below, the former generally measuring five and the latter three lines. Bischoff (Nervi Accessorii Willisii Anatomia et Physiologia, 1832, p. 20) gives the same measurements as those of Arnold, from whom he has evidently copied them. Bendz (De Connexu inter Nervum Vagum et Accessorium Willisii, 1836, p. 17) describes it as a rounded ganglion, somewhat flattened, measuring about two lines in the antero-posterior diameter, and nearly two lines in the vertical direction. Valentin (Söemmerring's Vom Baue des Menschlichen Korpers, Hirn und Nervenlehre. Vierter Band. 1841. S. 482) describes it as an oblong rounded swelling, somewhat flattened, and about from a line and three quarters to two and a half lines in length.

† Edinburgh Medical and Surgical Journal, No. 153, 1842.

‡ Remak (Froriep's neue Notizen for 1837, No. 54) states that some of the filaments of the vagus do not pass through this *superior ganglion* of the vagus in the dog, cat, and rabbit; and Volkmann (Müller's Archives, Heft v. 1840) confirms this observation of Remak on the dog; and further mentions that the same enlargement exists in the sheep, while in the calf all the filaments pass through the ganglion. The accuracy of such dissections, especially those made on the human species, and the physiological inferences deduced from them, have been called in question, (e. g. Hein in Müller's Archives for 1844, p. 336, and Bischoff, in the same work for 1833, p. 156), on the grounds that this anatomical arrangement is not constant, and besides that it is difficult to distinguish between the lower fibres of the root of the vagus and the upper fibres of the root of the nervus accessorius.

§ Bendz describes and delineates (De Connexu inter Nervum Vagum et Accessorium Willisii. Tab. i. Hauniæ, 1836) two small communicating filaments passing between the spinal accessory and the ganglion jugulare of the vagus. Valentin (Söemmerring Vom Baue des Menschlichen Korpers, Hirn und Nervenlehre. Vierter Band, 1841) describes a similar anastomosis. Arnold (Icones Nervorum lower and external part of this ganglion a small nerve arises, *(ramus auricularis nervi vagi,)* which is seen joined by another small branch from the lower part of the ganglion petrosum of the glosso-pharyngeal.* The ramus auricularis proceeds outwards and a little backwards anterior to the jugular vein, and lies in a groove in that portion of the petrous portion of the temporal bone which assists in forming the fossa jugularis, perforates the osseous partition between the fossa jugularis and the aqueduct of Fallopius, and enters the internal side of the latter about one or two lines above its lower termination in the stylo-mastoid foramen. It now divides itself into two branches, a small ascending twig which joins the portio dura nerve, and a larger portion which enters a canal on the external side of the aqueduct of Fallopius, proceeding outwards and a little backwards through that portion of the spongy portion of the temporal bone which forms the lower wall of the external meatus. The larger branch subdivides into two other branches as it lies in this canal. One of these emerges upon the external surface of the cranium through a small opening between the mastoid process and the posterior margin of the meatus auditorius, and divides into two or three twigs, which pass through openings in the cartilage of the pavillon of the external ear, and are ultimately distributed upon the tegumentary covering of the internal surface of the concha and meatus auditorius externus. The other branch of the nerve passes through the mastoid process and joins itself to the auricular branch of the portio dura, and along with it is distributed upon the posterior surface of the pavillon of the external ear.† The trunk of the spinal accessory is closely connected to the posterior surface of the superior ganglion of the vagus by cellular tissue, and immediately below the lower end of the ganglion it throws a considerable branch into the vagus. The exact place and manner in which these auxiliary fibres from the accessory join the vagus differ in different individuals, and sometimes in the two sides of the same individual, but most generally the spinal accessory divides itself at the lower part of the foramen lacerum into two branches, the *internal* and *external branches of the spinal accessory.* The internal branch runs immediately into the anterior and outer part of the vagus, and while one portion of its fibres goes to form a part of the *superior pharyngeal branch* of the vagus, the other portion joins itself to the trunk of the vagus, and accompanies it down the neck. Sometimes the fibres of the internal branch of the accessory are arranged in two bundles, and in such cases the one generally joins itself to the vagus a little below the other. The *external branch* of the accessory proceeds downwards and outwards, perforates the upper part of the sterno-cleido-mastoid muscle, and ultimately terminates in the trapezius muscle.

The superior ganglion of the vagus was known to Ehrenritter.* It appears also to have been well known to Wutzer, for it is both mentioned and figured by him in his monograph De Corporis Humani Gangliorum Fab. et Usu, 1818. Wutzer has in fig. vii. certainly represented it as being placed somewhat inferior to the ganglion petrosum of the glosso-pharyngeal, instead of being rather above it: yet as he terms it ganglion primum n. v. and figures the ganglion secundum in its proper position, there can be no doubt that he was well aware of its existence. It has been supposed by some that Lobstein† had also pointed out the existence of this ganglion, while others maintain that his description is not sufficiently explicit to enable us to decide whether it refers to the upper or lower ganglion of the vagus. It appears, however, much more probable that it is the superior ganglion, for after mentioning that the vagus presents a reddish appearance, similar to a ganglion, (rubella parum quasi ganglion mentiretur,) he describes the superior pharyngeal branch of this nerve as arising below it. Müller‡ has attempted to shew that Comparetti was the first anatomist who described this ganglion, and that he was even acquainted with the ramus auricularis of the vagus; but Arnold,§ on the other hand, maintains, and we think justly, that the description of Comparetti applies equally well, if not better, to the ganglion petrosum of the glosso-pharyngeal. Desmoulins and Magendie‖ observed the superior ganglion of the vagus in the carnivorous Mammalia and in the Ruminantia, and also a branch passing from it to join the portio dura, but denied that this ramus auricularis exists in man. Cuvier¶ had also previous to this pointed out the ramus auricularis in the calf. It was not, however, until Arnold's description of this ganglion had been made public, that it became generally known to anatomists, and its true nature and its anatomical relations exactly ascertained.** Ar-

Capitis, plate iv.) represents an anastomosis between the accessory and ganglion jugulare. Krause (Hanbuch der Menschlichen Anatomie. S. 1066, 1843, and Hein (Müller's Archives for 1844. Heft iv. p. 337) describe the superior filaments of the root of the accessory as connecting themselves to the lower filaments of the vagus, and that a few of the filaments of the accessory may enter the ganglion jugulare of the vagus. Bischoff (Nervi Accessorii Willisii Anatomia et Physiologia, 1832) neither delineates nor describes any communicating filaments passing between the spinal accessory and the ganglion jugulare of the vagus.

* In Valentin's description (opus cit. p. 483) of this auricular branch, the strengthening twig is said to come from the hypoglossal nerve, (aus dem zungenfleischnerven,) but this must either be some error of the press or some *lapsus scribendi*.

nold was the first who described the ramus auricularis in the human species.

Passage of the vagus along the neck to the origin of the inferior or recurrent laryngeal branch.—After the vagus emerges from the inferior aperture of the foramen lacerum posterius, it lies between the internal carotid artery and the internal jugular vein, the artery being internal and anterior, and at first separated a small distance from it, the vein being immediately posterior and external. The glosso-pharyngeal is still placed on its anterior side, but soon leaves it and crosses the anterior surface of the internal carotid artery on its way to the root of the tongue. The spinal accessory is still on its posterior side, but a little above the transverse process of the atlas the external branch begins to diverge backwards and outwards, and passes beneath the upper part of the internal jugular vein to reach the inner surface of the upper part of the sterno-cleido-mastoid muscle. The sympathetic nerve lies immediately posterior to it. The hypoglossal approximates its outer edge immediately below the foramen lacerum, gradually gets upon its anterior surface, is seen emerging from the angle left between it and the external branch of the accessory, where these nerves begin to separate, and opposite the transverse process of the atlas, or sometimes a little below this, it has crossed over its anterior edge, and proceeds forwards and inwards to reach the tongue. The hypoglossal, in crossing over the anterior surface of the vagus, is very closely bound to it by cellular tissue, and some small communicating branches pass between them. Some small communicating branches also pass between this portion of the vagus and the external branch of the spinal accessory, the superior ganglion of the sympathetic, the glosso-pharyngeal, and the nervous loop formed by the anterior branches of the first and second cervical nerves in front of the transverse process of the atlas. The vagus also in this part of its course generally sends a branch to join the descendens noni, and more rarely the descendens noni is almost entirely or altogether formed by this branch of the vagus.* All these nerves and bloodvessels in the upper part of the neck are surrounded and connected together by cellular devoid of adipose tissue. The vagus, after joining itself to the internal carotid artery, accompanies it to the point of bifurcation of the common carotid, and then continues its course down the neck, enclosed in the same sheath with the common carotid and internal jugular vein, the artery being internal, and the vein external and also anterior. The nerve maintains the same relation to these two vessels on both sides as far as the lower part of the neck, where on the right side the artery and vein diverge from each other, the artery passing inwards and the vein outwards, to join itself to the vena innominata; while on the left side the vein and artery have scarcely separated from each other, when the junction between the former and left subclavian vein takes place. On the right side the nerve is seen lying in the interval between the internal jugular and the internal carotid, and while crossing the anterior surface of the right subclavian artery nearly at right angles, it sends off the right inferior laryngeal or recurrent nerve. On the left side it passes downwards into the thorax, still lying close to the outer side of the left common carotid; but as it proceeds onwards, it crosses obliquely the left subclavian artery near its origin, and passing over the transverse portion of the arch of the aorta, it there gives off the left inferior laryngeal nerve. On both sides it passes into the thorax beneath the vena innominata.

The vagus, on emerging from the foramen lacerum, is near to the outer edge of the rectus capitis anticus minor muscle and in front of the rectus capitis lateralis; in its passage down the neck it first crosses the anterior surface of the lateral part of the atlas, then proceeds along the anterior surface of the rectus capitis anticus major muscle, and lastly it descends upon the longus colli. In the upper part of its course it lies deep, and crosses beneath the styloid process of the temporal bone and stylo-pharyngeus muscle. In the middle of the neck the two vagi nerves have approached nearer to each other, and are much more superficial. In the lower part of the neck they are again placed deeper, and are covered by the sterno-hyoid, sterno-thyroid, and sterno-cleido-mastoid muscles.

As the vagus emerges from the lower part of the foramen lacerum, its fibres are arranged somewhat loosely together, and are not enclosed in any dense and compact neurilema, so that it is larger here than at the lower part of the neck; and when the cellular tissue surrounding it is removed, the outline of the superficial fibres can be readily traced. About half an inch below the lower edge of the *superior ganglion* it enlarges still more, forming an oblong rounded swelling, from nine lines to an inch in length, and extending from about the transverse process of the atlas to midway between the transverse processes of the second and third cervical vertebræ *(plexus gangliformis nervi vagi, ganglion secundum n. v. of Wutzer, ganglion trunci n. v. of Bendz, ganglion inferius n. v.)* In the human species, though this swelling has a greyish colour, yet its appearance is that of a plexus more than of a true ganglion; and Valentin states* that he has not yet obtained satisfactory evidence that it contains the ganglionic nucleated globules without the presence of which there can be no true ganglion, and he believes that the greyish

* Krause (Handbuch der Menschlichen Anatomie, S. 1053 & 1063. Hannover, 1842) states that probably these strengthening filaments of the vagus furnish the cardiac branch of the descendens noni.

* In many of the Mammalia this swelling is more circumscribed and less elongated than in the human species, and forms a very distinct and true ganglion. Bischoff (oper. cit. tab. ii.) has given representations of it in the cat, fox, sow, mole, and weasel; and Mr. E. Cook, (Guy's Hospital Reports, vol. ii. p. 311,) in the guinea-pig, dog, and sheep. In all these animals it occupies that part of the trunk of the vagus from which the superior laryngeal nerve arises.

appearance of this swelling depends upon fat globules placed in the intervals of the plexus. At the lower part of this gangliform enlargement the nerve becomes smaller, rounder, firmer, and of a whiter colour.* This inferior or second ganglion of the vagus has been long known. Fallopius† speaks of an oblong olivary swelling on the vagus soon after its exit from the cranium. Willis ‡ has described it in the following words: "nervi truncus, ibidem major factus, in tumorem quemdam corpori calloso, seu ganglio similem, attolli atque excrescere videtur," and in fig. ix. he has delineated it under the name of "plexus gangliformis paris vagi." Vieussens§ also describes and figures it, and terms it "plexus gangliformis cervicalis nervi octavi paris." Winslow‖ describes it as "une espece de ganglion." It has also been described by Prochaska,¶ Wutzer, Scarpa, Bellingeri, &c. Some have considered it to be a true ganglion, others only a plexus. Some restrict the term of inferior ganglion to that portion of the enlargement of the nerve *immediately below* the origin of the superior laryngeal nerve, and have described it as being placed upon the internal fibres only, so that, according to this view, some of the external fibres of the vagus and the strengthening fibres of the spinal accessory do not pass through it.

The vagus in its passage down the neck gives off *pharyngeal*, *laryngeal*, *æsophageal*, *cardiac*, and *vascular* branches.

Superior pharyngeal branch (ramus pharyngeus seu primus n. v.)—This is by much the largest and most important pharyngeal branch of the vagus, and is frequently designated, *par excellence*, the pharyngeal branch of the vagus. It arises from the anterior surface of the vagus shortly after its exit from the foramen lacerum, and opposite the upper part of the atlas, and is evidently formed by fibres, partly from the internal branch of the accessory, and partly from the vagus. Generally the greater part of its filaments, occasionally nearly the whole, appear to come from the accessory. It passes inwards and a little downwards across the anterior surface of the internal carotid artery, to which it is generally pretty closely connected by cellular tissue, and lies a little inferior to the glosso-pharyngea lnerve.** Immediately after crossing the internal carotid, it passes over the ascending pharyngeal artery, and after a short course it reaches the surface of the middle constrictor muscle of the pharynx. As it is crossing the carotid it is generally joined by one, two, or three small branches descending from the glosso-pharyngeal, and at the point of their junction a small plexus or ganglion is formed on the pharyngeal. (Vide article GLOSSO-PHARYNGEAL NERVE.) At this point the pharyngeal generally divides into several branches.* Two of these are considerably larger than the others, and one of them passes inwards and upwards, and the other inwards and downwards over the lateral surface of the pharynx; while the smaller branches, two or more in number, pass upon the surface of the internal carotid and neighbouring bloodvessels, especially the arteria pharyngea ascendens, to assist in forming the nervous plexuses surrounding them. The two larger branches which pass upon the surface of the pharynx are soon joined by branches from the superior ganglion of the sympathetic. The upper branch passes over the superior pharyngeal constrictor to its upper edge, sending filaments to that muscle, to the elevator palati, the palato-pharyngeus, the azygos uvulæ, and also to the stylo-pharyngeus, and anastomoses freely with the pharyngeal and tonsillitic branches of the glosso-pharyngeal nerve and twigs of the sympathetic coming from its superior cervical ganglion. The lower runs downwards over the surface of the middle and inferior constrictors, distributes twigs to these muscles, and anastomoses with the *inferior pharyngeal* branch of the vagus, the pharyngeal branches of the superior laryngeal, and with some filaments of the sympathetic.

Inferior pharyngeal branch (ramus pharyngeus inferior).—This branch arises a very little below the last, and runs parallel to it and across the anterior surface of the internal carotid. It is joined by a considerable branch from the superior ganglion of the sympathetic, which generally forms an arch with it around the ascending pharyngeal artery. It soon divides itself into different branches, which are distributed upon the lower part of the middle constrictor muscle, and over the whole of the inferior constrictor, and anastomoses with the twigs of the other nerves found on the surface of these muscles.

Valentin describes under the name of *middle pharyngeal nerves (rami pharyngei medii seu tenuiores n. v.)* some small filaments arising from the anterior surface of the vagus immediately below the superior pharyngeal, and which pass forwards to join the pharyngeal branches of the glosso-pharyngeal. The free anastomosis of the nerves we have mentioned, viz. the glosso-pharyngeal and sympathetic, with the numerous subdivisions of the pharyngeal branches of the vagus, intermixed with a few twigs from the superior laryngeal, and also with some small filaments from the upper part of the cervical plexus of nerves, and an occasional twig from the hypo-glossal, form an elongated and intricate plexus (plexus pharyn-

** Cruveilhier (Anatomie Descriptive, tom. iv. p. 958, 1836,) describes the pharyngeal branch as passing behind (derrière) and not in front of the internal carotid. Cloquet (Traité d'Anatomie Descriptive, 2de partie, p. 620,) also described it as passing behind the internal carotid. No doubt this nerve may occasionally pass behind the artery, and similar varieties are to be found in the course of all nerves; but it is equally certain that its *usual* course is in front of the artery, and this inaccuracy must have occurred through some inadvertency.

* Wrisberg (De Nervis Pharyngis, Ludwig's Script. Min. Nerv. Sel. tom. iii. p. 58) describes five branches radiating from the ganglion pharyngeum.

geus) upon the lateral surface of the pharynx. (See article GLOSS-PHARYNGEAL NERVE.)

Superior laryngeal branch (ramus laryngeus superior) arises from the inner side of the vagus, about four or five lines below the superior pharyngeal branch, and from the upper and inner part of the *second* or *inferior* ganglion. It is considerably larger than the pharyngeal branch, and in the first part of its course proceeds almost directly inwards, then inwards and downwards, passing behind the internal carotid and in front of the longus colli muscle.* While it is behind the carotid it generally divides into its two branches, the *internal* and *external*. The internal is much the larger and more important, crosses the lateral part of the middle constrictor of the pharynx obliquely downwards, forwards, and inwards, joins itself to the laryngeal branch of the superior thyroid artery and runs along its upper edge, passes between the lower margin of the os hyoides and upper margin of the thyroid cartilage, and reaches the upper edge of the larynx by perforating the thyro-hyoid ligament posterior to the external edge of the thyro-hyoid muscle, above the upper edge of the inferior constrictor and below the lower edge of the middle constrictor of the pharynx, and a little in front of the round ligament connecting the superior cornu of the thyroid cartilage to the larger cornu of the hyoid bone. Sometimes one or two small twigs pass between the trunk of the vagus and the superior laryngeal soon after the origin of the latter, and the external branch of the superior laryngeal occasionally comes directly from the trunk of the vagus, a little below the origin of the internal branch. While the superior laryngeal nerve is passing behind the internal carotid, it sends off several small twigs, some of which communicate with the pharyngeal plexus, a few pass downwards and throw themselves into some of the cardiac nerves, and the greater part run upon the surface of the internal and external carotids, and assist in forming, with the more numerous branches from the sympathetic, the arterial plexus of nerves winding round the carotid arteries and their branches.

External branch of the superior laryngeal. It is strengthened by some twigs from the superior ganglion of the sympathetic, passes downwards and forwards over the inferior constrictor muscle of the pharynx and lateral surface of the larynx, gets below the outer edge of the sterno-thyroid, and continues its course below it and the thyro-hyoid muscle. It gives some twigs to the inferior constrictor muscle, some filaments also to the upper part of the sterno-hyoid and thyroid muscles, and to the thyroid body. The continuation of the nerve after sending a twig downwards to anastomose with another twig from the inferior laryngeal nerve behind the thyroid body, ultimately terminates in the crico-thyroid muscle.†

Internal branch of the superior laryngeal. As soon as this branch has perforated the thyro-hyoid ligament and reached the outer surface of the mucous membrane immediately beneath it, it divides into numerous branches which are flattened and radiating, some passing upwards and forwards towards the base of the tongue and sides of the epiglottis, others forwards, downwards, and inwards in the aryteno-epiglottidean folds to the surfaces of the epiglottis, and others downwards upon the posterior surface of the larynx. The branches which proceed forwards and upwards are small and pass onwards to the glosso-epiglottidean folds; and while some of their filaments terminate in these folds and in the mucous membrane at the lateral and back part of the tongue, others turn inwards and are distributed upon the submucous glands and the mucous covering of the anterior and upper part of the epiglottis. Several pretty strong branches pass forwards and inwards in the aryteno-epiglottidean folds to the side of the epiglottis. Some of these proceed upon its anterior surface and are there distributed upon the mucous membrane and the submucous glands, sending also a few filaments through small apertures in the epiglottis to be ramified in the mucous membrane on its posterior or laryngeal surface; while other branches pass upon the posterior aspect of the epiglottis,—some of them occupying notches on its outer edge,—and are distributed upon the submucous glands and mucous membrane covering that surface. A few branches proceed downwards and forwards over the outer surface of the lining mucous membrane of the larynx, send some filaments to the laryngeal sac, and may be traced as far as the inferior or true vocal chords. A long slender branch passes downwards on the outer surface of the thyro-arytenoid muscle, and between it and the inner surface of the thyroid cartilage, and frequently anastomoses with an ascending branch of the recurrent or inferior laryngeal. One or two slender filaments enter the thyro-arytenoid muscle, and these, after a long and winding course among the fibres of that muscle and those of the crico-arytenoideus lateralis, ultimately run to the mucous membrane of the larynx. A pretty large branch runs backwards in the posterior part of the thyro-arytenoid fold of mucous membrane, transmitting at the same time a few filaments downwards; and on reaching the arytenoid cartilage it sends several filaments upon the posterior surface of the proper arytenoid muscles, and continuing its course downwards between the mucous membrane of the pharynx and the crico-arytenoideus posticus muscle, it anastomoses with one of the posterior ascending branches of the recurrent. The greater part of the filaments which enter among the fibres of the arytenoideus posticus and transversus muscles may be traced to the mucous membrane of the larynx, and only a very few appear to terminate among the muscular fibres; others anastomose with arytenoid

* The superior laryngeal nerve rarely passes in front of the internal carotid.

† A small twig from the external branch of the superior laryngeal perforates the thyroid cartilage occasionally, and anastomoses with some of the descending branches of the internal branch of the same nerve.

branches of the superior laryngeal of the opposite side, and with the arytenoid branch of the recurrent; and occasionally a filament perforates the arytenoid cartilage to reach the inner surface of the larynx.

Vascular and cardiac branches.—The vagus in its passage along the neck sends off directly from its trunk several filaments, which throw themselves into the arterial nervous plexuses surrounding the carotid arteries and their branches; and also others which pass downwards and join themselves, either directly or indirectly, to the cardiac plexus. These branches are very variable in their number, size, and origin, so that it is impossible to give any description of them which will be found generally applicable, and they commonly differ on the two sides in the same individual.

Vascular branches (rami vasculares).—Several small branches arise from the trunk of the vagus between the origin of the superior laryngeal nerve, and about a line or so below the level of the bifurcation of the common carotid, and chiefly pass upon the carotid arteries and their branches. Valentin* has divided these into—

1. *Rami carotici*, consisting of two or three larger and some smaller twigs, coming off from the vagus near the origin of the superior laryngeal and also from the commencement of the superior laryngeal. They run inwards and forwards upon the internal carotid.

2. *Ramus ad divisionem arteriæ carotidis* is principally distributed upon the common carotid at its bifurcation.

3. *Rami vasculares posteriores et interni* are generally three in number, come from that part of the trunk of the vagus on a level with the bifurcation of the common carotid, and run principally, as their name implies, to the nervous plexus on the posterior and inner part of the large neighbouring arteries.

4. *Rami vasculares anteriores et interni* spring from the trunk of the vagus a very little below the origin of the last, run to the outer side of the common carotid, and assist with some of the other branches of the vagus and sympathetic in forming a nervous network on the outer and anterior side of this artery, while one or more twigs proceed downwards to join the superior cardiac nerve of the vagus.

Cardiac nerves.—Two or three cardiac branches come from the inner side of the vagus at some little distance from each other; the upper of these generally arises a little below the bifurcation of the common carotid. These branches proceed downwards and inwards, communicate freely with each other, send some filaments upon the surface of the common carotid artery, anastomose freely with the cardiac branches of the superior and middle cervical ganglia of the sympathetic and with the recurrent, pass chiefly in front of the large arteries at the root of the neck, and terminate in the upper part of the cardiac plexus of nerves. Frequently, more especially when the upper cardiac branches are small, or when some of them are wanting, we find a pretty large cardiac branch arising from the vagus about the upper part of the lower third of the neck, and passing downwards, on the right side in front of the subclavian, on the left in front of the arch of the aorta, it throws itself into the upper part of the cardiac plexus. Two or more branches also leave the trunk of the vagus as it passes the subclavian on the right and the arch of the aorta on the left side, pass inwards and throw themselves partly into the cardiac plexus and partly into the anterior bronchial plexus.

Inferior laryngeal or recurrent branch.—(*Ramus laryngeus inferior seu recurrens.*) On the right side the recurrent arises from the vagus as it is passing over the anterior surface of the subclavian artery, while on the left side it is sent off from the vagus, generally from its inner side, as it is crossing the anterior surface of the transverse portion of the arch of the aorta. On the right side it hooks round the subclavian on the inner side of the scalenus anticus muscle, and passing upwards and inwards, first below the subclavian artery and then below the common carotid, it reaches the right side of the trachea. On the left side it hooks round the arch of the aorta and obliterated ductus arteriosus, and passing upwards and inwards below the aorta, the left subclavian at its origin, and the left common carotid, it reaches the left side of the trachea. The recurrent soon after its origin generally receives one or two additional twigs from the trunk of the vagus. Immediately after it leaves the trunk of the vagus, it anastomoses freely with branches of the sympathetic, chiefly with the internal branches of the two inferior cervical and first dorsal ganglia of the sympathetic,—and while the right sends some twigs upon the outer surface of the subclavian artery, the left sends some upon the surface of the aorta. It also throws several twigs into the cardiac, tracheal, and bronchial plexuses. The left sends some twigs to the tracheal plexus, while the corresponding twigs of the right side come from the trunk of the vagus. The two recurrents then proceed upwards along the sides of the trachea towards the larynx,—the left resting upon the anterior surface of the œsophagus,—and are both covered by the sterno-hyoid and sterno-thyroid muscles. In this part of the course of the recurrent it generally receives communicating twigs from the cardiac branches of the superior and middle cervical and sympathetic ganglia, and it also anastomoses with some of the upper cervical cardiac branches of the vagus. It also sends several twigs to the œsophagus and trachea, (*œsophageal and tracheal twigs of the recurrent,*) some of which perforate the fibrous membrane between the cartilaginous rings of the trachea, and reach its mucous surface, while others are distributed among the muscular fibres which complete the cartilaginous rings behind. As it approaches the larynx it sends a twig upwards and forwards, which anastomoses with a descending twig of the external branch of the superior laryngeal; and it gives some filaments to the thyroid body, to the mucous membrane of the lower part of

* Op. cit.

the pharynx, to the inferior constrictor of the pharynx, and also occasionally one or two slender filaments to the crico-thyroid muscle. It likewise sends a branch upwards over the posterior surface of the larynx, first passing between the œsophagus and back part of the trachea, and then beneath the mucous membrane of the anterior part of the pharynx and crico-arytenoideus posticus muscle, sending some filaments to the œsophagus and mucous membrane of the pharynx, and anastomosing with the posterior descending twig of the *internal branch* of the superior laryngeal. The trunk of the recurrent now passes upwards in front of the lower edge of the inferior constrictor muscle, gets into the sulcus on the posterior surface of the articulation between the lower cornu of the thyroid cartilage and the external surface of the cricoid cartilage, and then passes along the outer edge of the crico-arytenoideus posticus upon the external surface of the crico-arytenoideus lateralis and thyro-arytenoid muscles, where it terminates. In its course along the side of the larynx it generally sends a twig upwards to anastomose with one of the descending twigs of the *internal branch* of the superior laryngeal. As it is passing the crico-arytenoideus posticus it sends some twigs into the external edge of that muscle, all of which enter among its fibres except one. This last twig, which does not enter among the fibres of the muscle, runs beneath its outer edge, and proceeding upwards and inwards between its anterior surface and the posterior surface of the cricoid cartilage, it reaches the lower edge of the arytenoideus obliquus and transversus, and is lost among their fibres. As the *continuation* of the *recurrent* passes over the surface of the cricoid-arytenoideus lateralis, it sends some filaments inwards among the fibres of this muscle, and then proceeds upwards upon the thyro-arytenoid, into the interior of which it dips. Its terminating filaments are distributed in the thyro-arytenoid muscle, and a few only can be traced to the lining membrane of the larynx. We have thus seen, that while nearly all the filaments of the internal branch of the superior laryngeal, distributed to the larynx, ultimately run to its mucous surface, the greater part of the filaments of the recurrent are distributed in the muscles which are attached to and move the arytenoid cartilages.

The peculiarity in the course of the inferior laryngeal from which it derives its name of *recurrent*, depends upon the changes in the relative position of the branchial arteries to the larynx in the embryo, after they have assumed the form presented in the adult by the arch of the aorta and the large vessels which spring from it. In those cases where the right subclavian artery, instead of arising along with the right carotid by a common trunk (arteria innominata), comes off from the arch of the aorta beyond the origin of the left subclavian, or, in other words, is the last in order of the large arteries which supply the head and thoracic extremities, and then proceeds across the spine behind the œsophagus to reach its usual position behind the scalenus anticus muscle on the right side, the recurrent does not arch round the right subclavian, but is given off from the trunk of the vagus as it is passing the larynx.*

Course of the vagus through the thorax.—After the *right* vagus has given off the recurrent, it passes behind the ascending portion of the arch of the aorta, and proceeding downwards, inwards, and backwards behind the right bronchus, right pulmonary artery and veins, reaches the œsophagus as it lies in the posterior mediastinum. The *left* vagus, after passing from the anterior surface of the arch of the aorta, also proceeds downwards, inwards, and backwards behind the left bronchus, left pulmonary artery and veins, and also reaches the œsophagus in the posterior mediastinum at the same part where the right vagus joins it. Both nerves closely accompany the œsophagus down the posterior mediastinum, and pass from the thorax into the upper part of the abdomen through the same opening (œsophageal opening) in the diaphragm. At the upper part of the chest, the vagi become flattened from before backwards, and are consequently broader and thinner than in the neck.

Immediately after the vagus has given off the recurrent it sends numerous twigs inwards. Some of these pass upwards and inwards to assist in forming the cardiac plexus; some proceed transversely inwards upon the anterior surface of the lower part of the trachea, and anastomose with other branches from the vagus arising higher up, and also with branches from the recurrent and sympathetic to form the anterior and inferior tracheal plexus (plexus trachealis anterior et inferior); while others pass upon the posterior surface of the lower part of the trachea, anastomose with other branches from the recurrent and sympathetic, and thus form the posterior and inferior tracheal plexus. The vagus at this part also sends a few twigs upon the upper part of the thoracic portion of the œsophagus, forming a free anastomosis on its surface with other twigs from the recurrent and the posterior bronchial plexus (plexus œsophagei thoracici superior). It likewise sends some branches inwards and downwards to throw themselves into the lateral portion of the lower part of the cardiac plexus; while a few others pass still more downwards to reach the anterior

* Two cases of this variety, in the origin and course of the inferior laryngeal nerve and right subclavian artery, are recorded by Dr. Stedman (Edin. Med. and Surg. Journal for 1823, p. 564) and Dr. Hart (in same Journal, 25th vol. 1826). I have myself had an opportunity of examining two cases of this kind. In those cases of double monstrosity where the head and larynx are double, and the two bodies are fused together immediately below this, so that the lower part of the neck, the thorax, and thoracic extremities are single, and where consequently we have four vagi nerves in the upper part of the neck, and only two at the lower part, the right recurrent of the right larynx hooks round the subclavian artery, and the left recurrent of the left larynx hooks round the arch of the aorta, while the other two vagi, or the left recurrent of the right larynx, and the right recurrent of the left, give off their superior laryngeal branches as they pass the larynges. I had an opportunity of dissecting one case of this kind.

surface of the pulmonary veins and branches of the trunk of the pulmonary artery, and anastomose with branches from the inferior part of the cardiac plexus prolonged upon these vessels. Other branches proceed downwards and inwards upon the anterior surface of the bronchii, and anastomose with the descending branches of the anterior and inferior tracheal plexus, with the nervous filaments accompanying the pulmonary bloodvessels, and with some branches direct from the sympathetic to form the anterior pulmonary plexus (plexus pulmonalis anterior). A few twigs also proceed from this portion of the vagus into the anterior mediastinum, and are chiefly distributed in the thymus gland. As the trunk of the vagus passes behind the bronchus it sends off several pretty large branches upon the posterior surface of that tube, and also a few smaller ones upon the posterior surface of the pulmonary bloodvessels. These branches form a great part of the posterior pulmonary plexus (plexus pulmonalis posterior), and anastomose with twigs from the posterior and inferior bronchial, with some filaments from the superior thoracic œsophageal and the anterior pulmonary plexuses. The branches of the pulmonary plexuses, after sending off some nervous filaments which run for some distance below the pleura, (vide Reisseisen De Fabrica Pulmonum, 1822, tab. vi. plate 2,) accompany the bronchial tubes and bloodvessels into the interior of the lungs, and follow the divisions and subdivisions of the bronchial tubes. The two trunks of the vagi, after leaving the lower edge of the bronchi, soon reach the œsophagus, where each nerve divides into three or four chords upon the surface of the œsophagus; those formed by the subdivisions of the left vagus lying on its anterior and left side, those by the right vagus on its posterior and right side. The chords of the same nerve anastomose freely by large branches, and also by smaller and less numerous branches on both sides of the œsophagus, with those of the opposite nerve, and thus form an extensive and open network upon the surface of the œsophagus, called the inferior œsophageal plexus (plexus œsophageus thoracis inferior).* From these chords nervous filaments pass into the walls of the œsophagus, and they also exchange some communicating filaments with the sympathetic. Immediately before the vagi pass through the œsophageal opening of the diaphragm, the chords into which each nerve has divided again reunite; those of the left nerve collecting into one trunk, while those of the right frequently form two branches which run close to each other.† As they pass through the œsophageal opening, the right nerve, or the larger, is placed on the posterior surface of the œsophagus, and the left, or the smaller, on its anterior surface.*

Distribution of the vagus in the abdomen. Left vagus.—As it enters the abdomen it sends some small branches upon the anterior surface of the lower part of the œsophagus, some of which enter the walls of that tube, others anastomose with œsophageal twigs from the right vagus, and others are prolonged downwards upon the cardiac end of the stomach. As it proceeds downwards over the cardiac surface of the stomach it also passes towards the right side and forms a curve, the convexity of which looks to the left. From the convexity of this curve several small branches run across the anterior surface of the cardiac orifice and the upper part of the large *cul de sac* of the stomach, and some of these anastomose with filaments from the left portion of the solar plexus, and from the phrenic nerve.† From the concavity several small branches run upwards and to the right between the layers of the smaller omentum to join the left hepatic plexus.‡ The left vagus now divides itself into several branches, which pass towards the pyloric surface of the stomach, along the upper edge of the anterior surface of the stomach, very close to the smaller curvature of that organ, and along the lower edge of the coronary artery of the stomach, sending numerous filaments into the nervous plexuses of the sympathetic surrounding the coronary and superior pyloric arteries, and also branches downwards over the anterior surface of the stomach. These latter branches, after running a greater or less distance below the peritoneal covering of the stomach, penetrate the muscular coat where some of their filaments terminate, while others pass through it to reach the mucous coat. The few branches of the left vagus which reach the pyloric orifice are partly distributed upon the walls of that portion of the organ, and partly throw themselves into the cœliac plexus. Some of the filaments of the latter portion may be traced into the numerous plexuses surrounding the gastro-duodenalis branch of the hepatic artery, into the right hepatic plexus, and may sometimes be followed as far as the artery of the gall-bladder. The branches which leave the left vagus as it lies on the anterior surface of the lower part of the œsophagus, and cross the anterior surface of the cardiac orifice of the stomach, divide and subdivide below the peritoneum in a forked manner, and also anastomose freely with each other, forming a kind of plexus which has been termed the anterior cardiac plexus of the stomach. As the branches of the left vagus pass along the smaller curvature of the stomach, they not only anastomose freely with the plexuses of the superior coronary and superior pyloric arteries, but with each other, forming a plexus along the upper edge of the anterior surface of the stomach, stretching from the cardiac to the pyloric orifice,

* Some anatomists call that part of the plexus formed by the left vagus the *left œsophageal plexus*, and that formed by the right vagus the *right œsophageal plexus*.

† Wrisberg (Ludwig's Scrip. Nerv. Min. Select. tom. iv. p. 59) says, that he has seen the nervous chords of both vagi unite into a single trunk on the œsophagus, which again divided itself into two branches (right and left vagi) before passing through the diaphragm.

* Wrisberg (opus cit.) states, that the vagi send a few filaments to the diaphragm.

† Valentin, oper. cit. s. 500.

‡ Vide Swan's Demonstrations of the Nerves of the Human Body, plate viii. 1830.

which Valentin* has termed plexus gastricus anterior et superior.

Right vagus.—As the right vagus is entering the abdomen it sends numerous branches upon the posterior part of the termination of the œsophagus and of the cardiac extremity of the stomach. Part of these disappear in the muscular fibres of the œsophagus and stomach; others anastomose with the branches of the left vagus, while others proceed downwards and to the left side upon the posterior surface of the large cul-de-sac of the stomach, sending filaments into the muscular coat, and also anastomosing with the filaments of the splenic plexus accompanying the vasa brevia. The right vagus also sends some branches upon the posterior surface of the stomach, to be distributed in that part of the organ, a few of which proceed as far as the large curvature, and course along it from left to right. It also sends two or three branches along the smaller curvature, which anastomose with the coronary plexus and branches of the left vagus. A considerable portion of the right vagus,—so large as generally to present the appearance of being the continuation of the trunk of the nerve,—proceeds from the posterior surface of the cardiac region of the stomach, backwards and downwards to the left side of the cœliac axis, sending branches to the splenic, the coronary, and to the superior mesenteric plexuses, to the plexus surrounding the pancreatic branches of the splenic artery; and it ultimately terminates in the left semilunar ganglion. The branches of the right vagus running upon the posterior surface of the lower part of the œsophagus and cardiac orifice of the stomach have been termed the posterior cardiac plexus.† Dr. Remak has discovered numerous small ganglia upon the filaments of the cardiac nerves, as they are ramified upon the surface of the heart;‡ also upon some of the filaments of the pulmonary plexus, and upon some of the finer branches of the superior laryngeal nerve.§ These ganglia can scarcely be seen by the naked eye, and it is only when examined by the microscope that we can satisfactorily determine their nature. These ganglia appear to be placed upon the filaments of the sympathetic, conjoined with the branches of the vagi, and not upon those of the vagi.

According to Volkmann and Bidder the vagus nerve contains, in all vertebrated animals, a greater number of sympathetic than cerebro-spinal filaments; and this preponderance of the sympathetic over the cerebro-spinal is more marked in the lower than in the higher vertebrata. This remark is in conformity with the observations of E. H. Weber upon the relative size of the vagus and sympathetic in the different families of the vertebrata, from which it appears that in the lower vertebrata the vagus increases, the sympathetic diminishes, in size. The branches of the vagus distributed in the œsophagus, heart, lungs, stomach, liver, and gills, are chiefly composed of sympathetic filaments, while the recurrent one of the motor branches is chiefly composed of cerebro-spinal filaments.*

Connection of the vagus and spinal accessory. We have seen that, as the vagus and accessory emerge from the foramen lacerum posterius, the internal branch of the accessory joins itself to the vagus, and that while part of its filaments go to assist in forming the superior pharyngeal branch of the vagus, the rest proceed downwards with the trunk of the vagus, and become incorporated with it. Bischoff states† that he has not been able to trace the filaments of the accessory into any of the branches of the vagus except the pharyngeal, while Bendz‡ has been more successful. He states that the portion of the accessory which accompanies the vagus down the neck sends a few filaments to the upper part of the inferior ganglion of the vagus, and then joins itself to some of the posterior and external fibres of the vagus which do not pass through the ganglion. Below the ganglion these fibres form part of the trunk of the nerve, being enclosed in the same neurilema with those which pass through the ganglion. At the lower edge of the ganglion, or sometimes a little lower, the accessory portion sends off some filaments which often join the external branch of the superior laryngeal, but more frequently give twigs to the sterno-thyroid muscle. Other fibres of the accessory portion accompany the vagus into the thorax, and some of them assist in forming the recurrent nerve. Some small twigs from the accessory join the pulmonary and cardiac plexuses; the remainder accompany the vagus to the stomach, where they are lost. Mr. Spence states that those fibres of the vagus which do not pass through the superior ganglion are joined by the internal branch of the accessory; and that these together form a small flat band, which may be traced among the other fibres of the vagus to the lower part of the neck, where it is joined by some of the other fibres of the vagus which have passed through the ganglion, and seems to go principally to the formation of the recurrent nerve.

We have seen that the vagi are distributed over a large space and upon many organs. They send branches to the external ear, to the pharynx, the larynx, the œsophagus, the trachea, the thyroid body, the heart, the lungs, the stomach; also to the liver, the spleen, the pancreas, the small intestines, and probably to other viscera of the abdomen. In their course they communicate very freely and extensively with the sympathetic,§ and to a greater or less

* Opus cit. S. 503.

† Many anatomists describe the branches given off by both vagi near the cardiac orifice of the stomach as forming a single cardiac plexus, the larger portion of which is formed by the right vagus.

§ In many of the mammalia the cervical portion of the sympathetic joins the trunk of the vagus immediately below the inferior ganglion of the vagus.

extent with several of the other cerebro-spinal nerves, as the spinal accessory, the glosso-pharyngeal, the hypo-glossal, the portio dura, the two superior cervical, and sometimes with some of the lower cervicals. The vagi are very extensively ramified upon the internal tegumentary membrane, as the mucous membrane of the pharynx, larynx, œsophagus, stomach, trachea, and lungs, and send only one small branch, viz. the ramus auricularis, to the external tegumentary membrane. Many of its branches are distributed upon the muscular fibres surrounding the upper part of the digestive and respiratory tubes.

Physiology of the nervus vagus.—From the distribution of this nerve in so many of the most important organs in the body which it is impossible to insulate, or prevent their mutual actions and reactions upon each other, and from its numerous and intimate connections with several other nerves, investigations into its physiology are beset with unusual difficulties. As, however, its lesions are attended by the most serious derangements of the respiratory and digestive organs, and as a knowledge of its functions bears in a prominent manner upon many interesting questions both in special and general physiology, it has naturally attracted the frequent attention of the physiologist, and has been made the subject of numerous experimental investigations.

Do the roots of the vagus contain any motor filaments?—No one can for a moment doubt that the trunk of the vagus, in its course down the neck, does contain motor filaments, but there is every reason to believe that it derives at least the greater part of these from the spinal accessory. From the resemblance of the vagus and spinal accessory as they lie in the foramen lacerum posterius to the anterior and posterior roots of a spinal nerve,—the vagus with its superior ganglion corresponding to the posterior, and the spinal accessory to the anterior root,—many anatomists and physiologists have of late maintained that the roots of the vagus, like the posterior roots of the spinal nerve, contain no motiferous filaments. It is scarcely necessary to add, that the junction of the *internal branch* of the accessory and the vagus immediately beyond the superior ganglion of the latter, increases still further this resemblance between these and a spinal nerve. This opinion has been maintained on anatomical considerations alone, by Arnold, Scarpa, and Bendz,* and has been further strengthened by the experiments of Bischoff,† Valentin,‡ and Longet.§ It is on the other hand maintained, that this opinion is too exclusive, and that, though there can be no doubt of the greater part of the filaments of the roots of the vagus being incident and sensiferous, yet they do contain some motiferous filaments. We have seen that, probably both in man and in some of the other mammalia, a few of the filaments of the vagus do not pass through its superior ganglion, and consequently the anatomical argument is not so conclusive as it at first appears to be. An examination of the experimental proof adduced in favour of these two opinions shews that the former is chiefly founded upon negative, and the latter upon positive evidence. Müller* saw muscular movements of the pharynx follow excitation of the roots of the vagus within the cranium; but from having neglected some precautions in the performance of the experiment, he himself is not disposed to attach to it much weight. I have related some experiments in which I observed muscular movements in the pharynx, larynx, and œsophagus, from irritation of the vagus within the cranium, on the dog immediately after death.† Volkmann has performed similar experiments upon calves, sheep, goats, and cats, and perceived muscular contractions in the levator palati, azygos uvulæ, the superior and inferior constrictor muscles of the pharynx, the palato-pharyngeus, and crico-thyroid.‡ The experiments of Stilling,§ Wagner,|| Van Kempen,¶ Hein,** and Bernard†† are also all in favour of the opinion that the root of the vagus contains motor filaments.

* Tractatus de Connexu inter Nervum Vagum et Accessorium Willisii, Hauniæ, 1836. According to Müller, this idea of the resemblance of the anatomical arrangement of the vagus and accessory to a spinal nerve had previously suggested itself to Görres in his Exposition der Physiologie, 1809.

† Nervi Accessorii Willisii Anat. et Phys. 1832. Bischoff, however, has more lately satisfied himself by experiment that the root of the vagus does contain motor filaments.

† Edinburgh Medical and Surgical Journal, 1838.

‡ Müller's Archives, p. 493, for 1840. Volkmann expressly states that these muscular contractions were also observed on irritating the vagus within the cranium in the calf, though in that animal all the filaments of the vagus appeared to him to pass through its superior ganglion.

§ Stilling states that he saw movements of the pharynx, the glottis, and the stomach in two cats, on exciting the roots of the vagus within the cranium. Vide Bischoff's Bericht über die Fortschritte der Physiologie in Jahre 1842, in Müller's Archives for 1843. Heft vi. p. 154.

|| Lehrbuch der Physiologie. Dritte Abtheilung, S. 329. Leipzig, 1842.

¶ Van Kempen observed contractions of the constrictors of the pharynx, the palato-glossus, the œsophagus, and the interior muscles of the larynx. Essai Experimental sur la Nature fonctionelle du Nerf-pneumogastrique, Louvain, 1842. Vide also Bischoff's Bericht, &c. supra cit. pp. 154-5. Bischoff states (p. 155) that he himself observed movements of the soft palate, in which the contractions of the levator palati muscle were very decided, on the irritation of the roots both of the vagus and of the accessory.

** Hein observed contractions in the elevator palati, azygos uvulæ, and palato-pharyngeus, but in the last muscle less frequently than in the two former, on irritating the root of the vagus, and the same muscles were thrown into contraction by irritation of the root of the accessory. He also perceived contractions in the stylo-pharyngeus from irritation of the root of the glosso-pharyngeal nerve, as in the experiments of Mayo and Volkmann, Müller's Archives, Heft iii. 1844. S. 297.

†† Archives Générales de Méd. 1844.

We believe that we are justified in concluding from the evidence here adduced, that the vagus, even at its origin, and before it has received any fibres from the accessory, does contain a few motor filaments.*

We shall here make a few remarks upon the *immediate* effects of chemical and mechanical excitation of the trunk of the vagus as it lies in the neck, and then proceed to examine in detail the functions of its auricular, pharyngeal, laryngeal, œsophageal, cardiac, pulmonary, and gastric branches. When the trunk of the vagus has been exposed in the neck in a living animal, and is cut, bruised, or rendered suddenly tense by forcible stretching, the animal generally gives indications of severe suffering, while in some cases the animal remains quiescent, and, as far as we can judge, suffers little, if any.

There can be no doubt, from the distinct testimony of numerous experimenters,† that the trunk of the vagus does contain sensiferous filaments, but there are good grounds for believing that the application of chemical agencies or the infliction of mechanical injuries upon this nerve below the origin of its superior laryngeal branch, are not attended with the same amount of pain as would attend similar lesions of one of the ordinary spinal nerves. Dr. Marshall Hall and Mr. Broughton remarked, that when the compression of this nerve is continued "for a few moments, an act of *respiration and deglutition follows, with a tendency to struggle and cough.*"‡ Romberg observed excitation of the vagus in the neck in a horse produce cough;§ and it appears that Cruveilhier had made previously the same observation.‖ In some of the cases in which I made this experiment on dogs, I observed powerful respiratory muscular movements, but never succeeded in inducing cough. Longet has been equally unsuccessful in producing cough by this means.¶ The respiratory muscular movements which follow excitation of the vagus in the neck are not dependent upon any direct action transmitted downwards to the lungs or muscles of respiration, but upon a reflex action, as Dr. Marshall Hall pointed out, arising from certain impressions being carried upwards to the medulla oblongata by the incident fibres of the vagus, followed by the transmission of a motor influence outwards from this portion of the central organ of the nervous system along the motiferous nerves distributed in the muscles moved. The excitation and mechanical injury of the vagus in the neck induces various other results, some of which may be included among their *immediate* effects, such as those upon the movements of the intrinsic muscles of the larynx, the diminution of the frequency of the respirations, &c.; but these will be more methodically introduced among the remarks which we have to make upon the functions of the individual branches of the nerve.*

Auricular branch.—From the origin of this branch from the superior ganglion of the vagus, and from being partly distributed to the integuments of the pavillon of the external ear, it is probable that it is composed of sensiferous filaments. If the portion of this branch which throws itself into the portio dura be sensiferous, the portio dura may contain some sensiferous filaments as it issues from the stylo-mastoid foramen.†

Pharyngeal branches.—As a great part, sometimes nearly the whole, of the superior pharyngeal branch of the vagus comes directly from the internal branch of the spinal accessory, we may, on anatomical grounds alone, conclude that it contains motor filaments. In irritating this branch in dogs, both alive and immediately after death, we observed extensive movements of the muscles of the pharynx and soft palate without any distinct indications of pain. As, however, the animal must necessarily be sub-

* The opinion that the internal branch of the spinal accessory furnishes no motor filaments to the trunk of the vagus has been several times of late attributed to me. That this is a mistake, any one may satisfy himself by reading the account which I have given of these experiments, from which I drew the following conclusions. "That the internal branch of the spinal accessory assists in moving the muscles of the pharynx we are satisfied, not only from the experiments just stated, but also from those upon the pharyngeal branch of the *par vagum*. Of the probable destination and functions of the other filaments of the *internal* branch of the *accessory*, we cannot pretend to judge without more extended inquiries. We certainly do not consider that these experiments entitle us to assert that they are not motor filaments." Edinburgh Medical and Surgical Journal, vol. 173, 1838.

† We have elsewhere collected the statements of different authors on this point. (Edin. Med. & Surgical Journal for 1838-9.)

¶ Anatomie et Physiologie du Système Nerveux, &c. t. ii. p. 309.

* In some animals, as in the dog, the division or compression of the vagus in the neck is immediately followed by diminution of the pupil of the eye of that side, the protrusion of the cartilaginous membrane at the inner canthus over the inner part of the anterior surface of the eyeball, the retraction of the eyeball deeper into the socket, and a slight approximation of the eyelids; and subsequently by inflammation of the conjunctiva. Petit (Histoire de l'Academie Royale des Sciences, année 1727) was the first who observed these effects, and justly attributed them to injury of the sympathetic nerve. It is only in those animals in which the sympathetic joints itself to the vagus in the upper part of the neck, that the division or compression of the trunk of the vagus produces any change on the eye. Vide Edin. Med. and Surgical Journal, No. 140, for experiments on this subject by the author of this article, and Valentin's Treatise de Functionibus Nerv. Cereb. &c. p. 109.

† Arnold believes that the sympathy occasionally observed between the external ear and the lungs may be owing to this auricular branch of the vagus. He refers to some cases, where the presence of hardened cerumen, of a bean, of a pea, and other foreign bodies in the cartilaginous tube of the external ear, has induced long-continued cough and even vomiting. (Bemerkungen über den Baue des Hirns und Ruckenmarks, &c. S. 168. Zürich, 1838.) In some individuals coughing can readily be induced by irritating the inner surface of the meatus auditorius externus.

jected to considerable suffering before the nerve can be exposed, this result cannot be taken as a conclusive test that it contains no filaments of common sensation. We also found that division of this branch on both sides rendered the second stage of deglutition difficult, by paralysing the muscles of the pharynx. The morsels of food were forced through the now passive bag of the pharynx to the commencement of the œsophagus by the repeated efforts of the muscles of the tongue and those attached to the larynx and hyoid bone. From these facts, we concluded that the pharyngeal branches of the vagus are chiefly, perhaps entirely, composed of motiferous filaments, and that they convey outwards the motive influence by which the muscles of the pharynx and soft palate are excited to contraction in the reflex muscular movements of deglutition.* It is possible that they may also contain a few sensiferous and incident filaments. Valentin, on irritating these branches in different animals immediately after death, saw the pharynx contract in a marked manner through its whole length.†

Volkmann states, as we have already had occasion to mention, that various muscles of the soft palate and pharynx were thrown into contraction on excitation of the vagus within the cranium.‡ He further observes, that he could not perceive any movements in the muscles of the pharynx or soft palate on irritating the spinal accessory within the cranium. This last result is certainly one which we would not expect, but the remarks we have to make upon it will be more appropriately introduced in the article SPINAL ACCESSORY NERVE.§ Longet observed very marked contractions in the pharynx on galvanizing the pharyngeal branch of the vagus in the horse and the dog.‖ Though the experiments we have referred to, in illustration of the functions of the pharyngeal branches of the vagus, differ in some respects, they all agree in this, that extensive and active muscular movements of the pharynx may be produced by their excitation, and that they therefore contain many motor filaments. We have adduced some facts which would seem to shew that they contain few, if any, motor filaments.

Laryngeal branches.—When the *superior laryngeal* nerve is laid bare in a living animal and pinched with the forceps, the animal gives indications of severe suffering, while on repeating the same experiment on the inferior laryngeal the animal seldom gives any indication of suffering pain. When an opening is made into the trachea, and a probe introduced through it into the interior of that tube and passed upwards, it excites little or no uneasiness until it reaches the interior of the larynx, when violent paroxysms of coughing and signs of great uneasiness immediately follow. The division of the *inferior laryngeal* nerves has no effect in diminishing the severity of these paroxysms of coughing or in quieting the struggles of the animal, while they instantly cease on cutting across the *internal branch* of the *superior laryngeal nerves.* Before Magendie published his observations upon the functions of these nerves it appears to have been generally believed that the different intrinsic muscles of the larynx received motor filaments both from the superior and inferior laryngeal nerves. Magendie has, on the other hand, maintained that the *superior laryngeal* moves those muscles which shut the superior aperture of the larynx, and the inferior laryngeal those which open it, and he supposed that this view sufficiently explained the closure of the superior aperture of the larynx on the division of both inferior laryngeal.* We found that on applying different excitants to the *superior laryngeal* nerve before it gave off its *external branch* in several animals immediately after death, that the crico-thyroid muscle was thrown into powerful contraction and the cricoid approximated to the thyroid cartilage, while all the muscles attached to the arytenoid cartilages remained quiescent. On irritating the *inferior laryngeals* all the muscles attached to the arytenoid cartilages were thrown into contraction, and as the force of those muscles which close the superior aperture of the larynx preponderates over that of those which open it, the arytenoid cartilages were drawn forwards and inwards, and the superior aperture of the larynx was closed. By applying the excitation to the nerves for a short time and in rapid succession, the superior aperture of the larynx could be made to close and open alternately,—to close during the period of excitation and to open during the intervals,—and it was also remarked that the outward movement, or that of opening, was dependent upon the elasticity of the parts. The inferences from these results were strengthened by an examination of the anatomical distribution of the laryngeal nerves, and confirmed by experiments upon living animals.† From these and other facts related in the paper referred to, we arrived at the following conclusions. The *superior laryngeal* furnishes one only of the intrinsic muscles (the crico-thyroid) of the larynx with motor filaments, while it supplies nearly all the sensiferous and incident filaments of the larynx,

* Edin. Med. and Surg. Jour. 1838.

† De Functionibus Nerv. Cerebralium, &c. p. 17, 1839.

‡ Volkmann concludes, as we have already mentioned, from his experiments that the stylo-pharyngeus and middle constrictor muscle of the pharynx do not derive their motor filaments from the pharyngeal branch of the vagus, but from the glosso-pharyngeal. In the article GLOSSO-PHARYNGEAL, we have stated, that, when this nerve is insulated carefully from the neighbouring nerves, no direct muscular movements follow its excitation. Valentin (opus cit. p. 38) and Longet (opus cit. tom. ii. p. 223) have from these experiments arrived at the same conclusions as we have on this point.

§ We may merely state in the mean time that Longet (opus cit. tom. ii. p. 27) has drawn from his experiments the conclusion that the spinal accessory furnishes all the motor filaments of the muscles of the larynx.

‖ Opus cit. tom. ii. p. 271.

† Edin. Med. and Surg. Jour., pp. 138, 139, 1838.

and also some of those distributed upon the pharynx and back parts of the tongue, so that it is chiefly composed of sensiferous and incident filaments. The *inferior laryngeal* furnishes incident and sensiferous filaments to the greater part of the trachea, to the cervical portion of the œsophagus, a few to the mucous surface of the pharynx, and still fewer to the larynx; it supplies the motor filaments of the cervical portion of the œsophagus and of all the muscles which are attached to and move the arytenoid cartilages, and is chiefly composed of motor filaments.* When any excitation is applied to the mucous membrane of the larynx in the healthy state, this does not excite the contraction of the muscles which move the arytenoid cartilages by acting *directly* upon these through the mucous membrane, but is the result, as Dr. M. Hall† had maintained, of a reflex or excito-motory action, in the performance of which the *superior laryngeal* is the incident, and the *inferior laryngeal* the motor nerve. In each recurrent nerve two sets of motor filaments are included, one set transmitting the nervous influence which stimulates the opening muscles of the larynx to act synchronously with the other muscles of inspiration, the other set transmitting the nervous influence which calls the closing muscles into synchronous action with the muscles of expiration.‡

Upon these views we can readily explain how, when the inferior laryngeal nerves are cut, all the movements of the muscles of the arytenoid cartilages are arrested, and the superior aperture of the larynx, as was first pointed out by Legallois, can no longer be dilated during inspiration. In fact, the sides of the larynx are not only no longer separated by an active influence, but are rendered quite passive, and yield readily within the limits of their natural movements to any external force applied to them. When the recurrent nerves are cut in an adult animal, where the cavity of the larynx is large, a quantity of air may still find its way through the diminished aperture, adequate, in many cases, to carry on the respiratory process in a sufficient manner, particularly if the muscles of inspiration are not acting violently. If, on the other hand, the capacity of the larynx be proportionally smaller as in young animals, the air rushes through the diminished superior aperture of the larynx in a narrower stream and with increased force, more especially when the inspiratory movements are powerful—or in other words, when the capacity of the thorax is suddenly and greatly enlarged,—and an insufficient quantity of air reaches the lungs. This quantity is still further reduced by the circumstance that the now passive sides of the superior aperture of the larynx are carried inwards by the current of air, and at each inspiration the arytenoid cartilages may be so closely approximated as to prevent the ingress of air and suffocate the animal. It is the inspiration alone of the animal which is difficult, for the expiration is easy. The occurrence or non-occurrence of dypsnœa, or suffocation, after section of the inferior laryngeals, is to be explained by the greater or less capacity of the larynx in the individual animal, and the activity and extent of its respiratory movements at the time. The *crowing sound* which frequently attends this condition of the larynx is a mere physical effect, and depends upon the current of air rushing rapidly through the diminished aperture of the larynx, and may be imitated in the dead larynx. Severe dyspnœa amounting to suffocation may arise both from the opposite conditions of irritation and compression of the inferior laryngeal nerves or the trunks of the pneumogastric above the origin of this branch. We have stated above that on irritating one recurrent nerve we observed that the arytenoid cartilages were approximated so as in some cases to shut completely the superior aperture of the larynx, and we have already explained how paralysis of this nerve by compression or any other cause should produce this effect by arresting the movements of all the muscles attached to the arytenoid cartilages.* We also found that after the section of both superior laryngeal nerves in dogs and rabbits they swallowed solids and fluids readily, and without exciting cough or difficulty of breathing.† Mr. Hilton has arrived at the conclusion, from the anatomical distribution of the nerves alone, that the superior laryngeal is chiefly sensitive, and that the only motor filaments which it contains are distributed in the crico-thyroid muscle, while the inferior laryngeal supplies all the muscles attached to the arytenoid cartilages with motor filaments,—a view in exact accordance with that which we have given above.‡

Volkmann in his experiments found that the movements of the glottis were not affected by dividing the superior laryngeal nerves.§ Longet||

* We also suggested that some of these filaments distributed in the trachea might be motor, though we had not succeeded in obtaining experimental evidence of it.

† Lectures on the Nervous System and its Diseases, Lecture 1, 1836.

‡ Each of these two sets may again be subdivided into other two—one composed of the excito-motory filaments of Dr. M. Hall, the other of sensifero-volitional filaments.

* Professor Henderson (Cormack's Journal of Medical Science, p. 10, for 1841) adduces cases to shew that in the human species the narrowing of the superior aperture of the larynx, termed laryngismus stridulus, may be induced both by irritation and paralysis of the recurrents.

† An account of the above experiments and inferences was read at the meeting of the British Scientific Association in 1837; a short epitome of them was given in the Athenæum for Sept. 16, 1837, and they were published in full in the Edinburgh Medical and Surgical Journal for January, 1838.

‡ Guy's Hospital Reports for October, 1837, forming part of the 2nd volume.

§ Opus. cit. Volkmann states that on irritating the external branch of the superior laryngeal in dogs and calves, not only the crico-thyroid muscle was thrown into contraction, but also the constrictor pharyngeus superior and the thyro-hyoid. If this be confirmed, these two last muscles must receive their motor nervous filaments from two sources, as the constrictor receives a supply from the pharyngeal branch of the vagus, and the thyro-hyoid from the hypoglossal.

|| Recherches Expérimentales sur les Functions des Nerfs, des Muscles du Larynx, &c. Paris, 1841.

has published various experiments upon these nerves very similar to those which we had performed, and obtained nearly the same results. Longet states that the respirations become increased in frequency after dividing the recurrents. Other experimenters have lately satisfied themselves of the accuracy of these experiments.

Effects of the laryngeal nerves on phonation.—The effect of the lesion of the recurrent nerves in enfeebling the voice was well known to Galen and the older physiologists.* We found in making this experiment that the voice, as Monro Secundus † and others have stated, is not altogether lost, for in some cases, at least, the animal could still emit a faint howl. Longet ‡ has observed that the voice is completely lost in old animals, while young animals are still able to produce acute sounds different from the natural voice if the crico-thyroid muscle moved through the *external* branch of the superior laryngeal be not paralysed, and he attributes this difference to the relative size of the larynx at these ages. We can have no doubts in attributing the effects of lesion of the inferior laryngeals upon the voice to the paralysis of the muscles attached to the arytenoid cartilages. §

Magendie mentions that an animal after section of the *superior laryngeal nerves* "loses almost all its acute sounds it acquires, besides a constant gravity which it had not previously."‖ This he attributed to the arrestment of the movements of the arytenoid muscles, but we have shown that the section of these nerves has no such effect. Bischoff could perceive no change upon the voice after he had divided these nerves in two dogs.¶ Longet states that the division of those nerves above the origin of the *external branch*, or of the external branch alone, is followed by a disagreeable hoarseness of the voice.** If the variations in the length of a tube alter the graveness and acuteness of the sounds which it emits, we would expect that the lesion of the superior laryngeals should, by arresting the movements of the crico-thyroid muscle, produce some change in this respect. Longet believes that the crico-thyroid muscles are, during their contraction, tensors of the vocal chords, and that the changes upon the voice induced by dividing the superior laryngeals depend upon the effect which paralysis of these muscles has upon the tension of the vocal chords.††

Œsophageal branches.—Muscular contractions have been observed in the œsophagus on irritating the trunk of the vagus, by Arnemann,* Cruikshank,† Mayo,‡ and others. When the trunk of the vagus is irritated above the origin of the recurrent, the muscular fibres of the œsophagus along its whole length are thrown into active contraction. In experiments upon rabbits we found that the œsophagus became impacted with food eaten after section of the vagi in the neck, when very little of it had reached the stomach and when no efforts at vomiting had occurred, while its muscular fibres could still readily be thrown into active contraction by *direct* excitation. From this we inferred that before the presence of the ingesta in this tube can excite its muscular fibres to contract and propel its contents onwards, the same conditions of the nervous system are necessary as for the production of the excito-motory movements, and that certain of the filaments of the vagi act as incident and others as motor nerves. That the food also collects in the œsophagus in the horse and sheep after division of the vagi may be inferred from the experiments of Dupuy § and others. In subsequent experiments upon dogs we found that substances seem to pass pretty freely along the œsophagus in that animal after section of the vagi. It would appear, however, that even in the dog the food is occasionally retained in the œsophagus after dividing the vagi.‖ Arnold (opus cit. p. 144) observed in his experiments upon hens and pigeons that the œsophagus and crop were so relaxed after section of the vagi that when the animals shook their head and neck, or kept the head in a depending position, a quantity of chyme flowed from the bill.

From a review of all these facts we are inclined to agree in the opinion lately expressed by Dr. M. Hall, that in some animals the muscular contractions of the œsophagus are excito-motory, while in others they are called into action by direct excitation. We cannot at present determine whether the propulsion of the food along the œsophagus in the human species partakes more of the former or of the latter class of movements. Magendie has ascertained that various muscular movements go on in the lower part of the œsophagus, more especially when the stomach is full, by which this tube is contracted during inspiration and relaxed during expiration, and that they are suspended by dividing the vagi. These we may class among the reflex muscular movements. The œsophagus is endowed with little sensibility, and in the natural and healthy condition of the organ the ingesta are propelled along it to the stomach without exciting any sensation. From a consideration of all the

above facts we believe that the œsophageal filaments are chiefly incident and motor, and a few of them only are sensiferous.

Cardiac branches.—We have in a former part of this work (article HEART) had occasion to state that several celebrated physiologists have failed in exciting the muscular contractions of the heart by irritation of the trunk of the vagus before it gives off its cardiac branches, or of these cardiac branches themselves. We have very frequently repeated this experiment upon animals immediately after death, and we have not been able to satisfy ourselves that galvanic and mechanical excitation of these nerves has any effect in renewing or increasing the contractions of the heart. No doubt we have not unfrequently seen the contractions of the heart become more frequent and vigorous during the performance of this experiment; but as similar changes in the strength and rapidity of its contractions are occasionally observed in an animal after death when no artificial excitant has been applied to these nerves, and from causes which cannot at present be explained, we did not think ourselves entitled to attribute these changes in the heart's action to the excitation of the nerves. Valentin* has stated that he has produced muscular contractions in the heart in different animals by irritation of the trunk of the vagus. He also states† that similar contractions of the heart were produced by excitation of the spinal accessory and of the three superior (sometimes also of the fourth) cervical nerves, and he maintains that the motor portion of the cardiac nerves comes from the spinal accessory and the superior cervical nerves. Longet‡ mentions that he failed in influencing the rhythm of the heart by the application of galvanism to the vagi in dogs, rabbits, and sheep, but very frequently succeeded by scraping the cervical cardiac branches of the vagus. Allowing that it is possible to increase the contractions of the heart by galvanic or mechanical excitation of the vagus or its cardiac branches, it must be admitted by every one that there is a very marked difference between the heart and voluntary muscles in this respect, for all those who have failed in their experiments on the nerves of the heart, have felt not the smallest difficulty in producing contractions of the voluntary muscles by excitation of their nerves. The increased frequency of the pulsations of the heart observed during and for some minutes after the division of the vagi may be fairly referred to the struggles and terror of the animal, and the feeble and rapid pulsation of the heart which precedes death from this experiment is not owing to any *direct* effect upon that organ. The sudden death occasionally remarked after the division of these nerves, and which some of the early experimenters attributed to arrestment of the contractility of the heart, was in fact dependent upon the suffocation of the animal by the suspension of the movements of the muscles which dilate the superior aperture of the larynx. We have related several experiments which appear to prove that when injuries of the brain and mental emotions affect the contractility of the heart, the nervous influence is not transmitted by the cardiac branches of the vagi alone, but may also pass along the filaments of the sympathetic or ganglionic system of nerves.

* Opus cit. p. 48, 62 and 66.
† Opus cit. p. 62.
‡ Opus cit. &c. tom. ii. p. 314.

Pulmonary branches.—Do the pulmonary branches of the vagus contain motor filaments? We have made various unsuccessful attempts to produce contractions in the muscular fibres of the bronchial tubes by excitation of the vagi in the neck.* Dr. C. T. B. Williams† was also unsuccessful on attempting this experiment, though he succeeded in producing contractions in the bronchial muscular fibres by their direct excitation, as by transmitting galvanism through the substance of the lungs, &c. Longet and Volkmann have not only succeeded in exciting contractions of the muscular fibres of the bronchii by direct stimulation, but also by excitants applied to the branches of the vagus.‡ To what extent are the pulmonary branches of the vagus sensiferous? Brachet relates some experiments which seem to prove that the sensation arising from the want of fresh air in the lungs, or the *besoin de respirer*, is annihilated by the division of vagi.§ Mr. Grainger‖ repeated one of Brachet's experiments, and seemed satisfied that his conclusions were correct. There are certain sources of fallacy attending the mode in which Brachet performed his experiments against which he has not taken the necessary precautions.

We have satisfied ourselves by numerous experiments that the *sense of anxiety* arising from the want of fresh air in the lungs continues after dividing the vagi when the access of air to the lungs is prevented;¶ and Volkmann** and Longet†† from their experiments have also arrived at the same conclusion. It is possible that certain impressions which may excite the *besoin de respirer* are conveyed upwards to the encephalon through the medium of the sympathetic, but it is more probable that in the conditions induced by the experiment it was more immediately dependent upon the circulation of ill-arterialized blood through the tissues of the body, and more especially through the encephalon. We do not mean to deny that impressions conveyed along the vagi to the encephalon may not excite the *besoin de respirer*; on the other hand, we believe that it is very probable that this sensation as first felt, when the respiration is suspended for a short time in the healthy condition of the body, is dependent upon impressions conveyed along this nerve. When,

however, the respiration has been suspended for a longer time and venous blood begins to circulate along the arteries, the other excitants of the *besoin de respirer* come into operation.

Brachet,* Krimer,† and Longet,‡ have from their experiments arrived at the conclusion that the sensations occasioned by irritation of the inner surface of the trachea and bronchial tubes, and which usually precede coughing, are annihilated by dividing the vagi. We have made repeated experiments on this point, and though we could not satisfy ourselves that these sensations were affected to the extent maintained by these authors, we believe that they are at least blunted.

To what extent do the filaments of the vagi act as incident nerves?—It has been proved by the experiments of Legallois,§ Flourens,|| and others, that all the respiratory and muscular movements cease on destroying the medulla oblongata, though the other parts of the encephalon situated above this may be injured in various ways without necessarily producing this effect. It is further well known that if the spinal chord be cut across, all the respiratory muscles are paralysed which receive their nerves from that portion of it below the point where it was divided, while those muscles which receive their nerves from that portion of the spinal chord still continuous with the medulla oblongata perform their usual functions. From these and other facts it may be considered as ascertained that all impressions made at the lungs and elsewhere capable of causing respiratory movements, must be conveyed to the medulla oblongata before they can produce any reflex excitation of the muscles of respiration. That the vagi can convey these impressions from the lungs is not only rendered probable from their attachment to the medulla oblongata, but may almost be considered as proved by the result of the experiments upon the spinal chord to which we have just referred. It, however, by no means follows that the vagi are the sole excitant nerves of respiration. It has been fully ascertained by numerous experimenters, more especially by those who have investigated the functions of this nerve from the time of Legallois, that an animal will continue to breathe after the division of both vagi in the neck, if care be taken to secure the ingress and egress of air to and from the lungs. It is now well known, as we have already had occasion to point out in examining the functions of the laryngeal branches, that if the vagi be injured above the origin of the recurrent laryngeals, none of the muscles attached to the arytenoid cartilages can any longer act in unison with the muscles of respiration, all their movements cease, and the superior aperture of the larynx can no longer be dilated during inspiration. If the larynx be large, and the animal refrain from any violent effort, an adequate quantity of air may still find its way to the lungs, and the respirations are at first performed with ease. If, on the other hand, the larynx be small, its superior aperture may be mechanically closed and the animal may be immediately suffocated, or the air may still pass through the larynx but in diminished quantity, and the animal may labour under dypsnœa from the moment the nerves are divided, up to its death. Even when means are taken to secure the free entrance of air into the lungs, an immediate and marked diminution in the frequency of the respiratory movements follows the division of both vagi in the neck. A. G. F. Emmert concluded, but apparently more upon theoretical grounds than from any direct observations made in the two experiments he had at that time performed on rabbits, that after lesion of the vagi the respirations become less frequent and prolonged.* Mayer reckoned the number of respirations, both before and at various periods after section of these nerves in five experiments upon the ass, dog, and rabbit, and found a very marked diminution in their frequency after dividing the nerves.† Mr. Broughton mentions, that in a horse in which the vagi were divided "the respirations became slow, twelve in a minute;" and in another horse "the respirations fell to five in the minute."‡ At what period after the division of the nerves these last observations were made, and what was the number of the respirations previous to the commencement of the experiments, we are not informed. Sir Astley Cooper has given the result of two experiments upon rabbits which well illustrate the effect of the division of the vagi upon the respiratory movements.§ In our experiments we ascertained that the diminution in the frequency of the respiratory movements, generally to less than half of their former number, is an *immediate* effect of the division of both vagi. The respiratory movements seem to be performed more slowly, and, generally, even from the first, in a somewhat heaving manner.|| Arnold in his experiments upon hens also observed a very considerable diminution in the frequency of the respiratory movements.¶ Brachet has asserted** that an animal continues to breathe after section of the vagi, because it has acquired the habit of using the respiratory muscles. Dr. Marshall Hall has maintained that after the vagi are divided the respiratory movements are no longer a function of the excito-motory but of the cerebral portion of the nervous system;††

and he has adduced in support of this view the statement of Cruveilhier that after the function of volition has been suspended by destroying the cerebrum, the respiratory movements are instantly arrested on dividing the vagi near their origin.* In putting this opinion to the test of experiment we found that though the respirations were very much diminished in frequency by the removal of the cerebrum and cerebellum and then dividing the vagi, they nevertheless continued for a longer or shorter time.† Similar results have also been subsequently obtained by Volkmann,‡ by Flourens,§ and by Longet.‖ From these facts we are entitled to conclude that the vagi are not the sole excitors of respiration, and that impressions may be made upon the medulla oblongata capable of exciting the involuntary respiratory movements after the vagi have been divided in the neck, and when impressions made on their expanded extremities in the lungs can no longer be conveyed inwards to the central organs of the nervous system. The importance of the vagi as incident nerves of respiration is not only proved by the marked and immediate diminution in the number of the respirations which follows their division,¶ but also in a more striking manner by the morbid changes which take place in the lungs.

Morbid changes in the lungs after dividing the vagi.—The injury or division of the vagi is almost always fatal after a few days, even when precautions are taken to secure the free ingress of air into the lungs. The period of death in such experiments varies in different animals. Rabbits generally die earlier than dogs. The greater number of dogs die before the third day, and comparatively few live beyond the fifth day. In seventeen experiments upon dogs we found that eleven died before the completion of the third day, and seven of these eleven before the completion of the second day. Longet says that he performed this experiment on thirty dogs, and they all died on or before the fifth day, and none of the rabbits operated on, lived beyond thirty-six hours.** Dupuy in his experiments found that horses lived to the fifth, sixth, and seventh day, when care was taken to admit a sufficient quantity of air into the lungs.†† De Blainville informs us that the pigeons on which he operated died on the sixth or seventh day;‡‡ and in the experiments of Arnold§§ upon hens and pigeons, these animals died between the second and fifth day. In general the lungs are the only organs found in an abnormal state after death from injury or division of the vagi. We found the lungs unfit for the healthy performance of their functions in fifteen out of seventeen dogs experimented upon. These organs are almost always more or less congested with blood, especially at the depending parts, and the bronchial tubes and air cells frequently contain much frothy serum. In some portions of the lungs the congestion of blood is occasionally so great as to render them dense and devoid of air. This condensation is not unfrequently greater in some parts than what can be accounted for by the mere congestion of blood in the vessels, and probably depends in a great measure upon the escape of the solid parts of the blood into the tissue of the lung. The frothy serum has frequently a greater or less deep tinge of red. Portions of the lung are likewise occasionally found condensed from pneumonic effusion. In seventeen experiments on dogs distinct evidences of pneumonia were observed in five, and in two of these it had run on to gangrene. These morbid changes upon the lungs are sufficient to explain the imperfect arterialization of the blood, and the diminished evolution of internal caloric which precedes death. We have endeavoured to prove that these morbid changes in the lungs are the result of the diminished frequency of the respiratory movements which immediately follows the division of the vagi. The vagi are the chief excitors of the respiratory muscular movements, and when they are tied or divided the respirations are instantly diminished to less than half their former number. The flow of blood through the lungs is dependent upon the continuance of the respiratory process, and the great diminution in the activity of the respiratory muscular movements must be followed by a retardation and congestion of the blood in the lungs. Such a congestion of blood, as is well known, is generally followed by an effusion of serum, and also predisposes the organs so circumstanced to various morbid changes, chiefly of an inflammatory nature. In the lungs this congestion is not only followed by the escape of the serum, but also of the more solid material from the vessels, rendering the tissue dense. The effused serum is mixed up with air moving along the bronchial tubes during inspiration and expiration, and it thus becomes frothy. A little blood may also exude from the congested mucous membrane of the bronchial tubes, giving the serum there effused a reddish tinge. As these changes proceed, the respiratory process becomes more and more imperfect, the blood flowing along the arteries approaches more and more to the venous hue, all the vital properties of the tissue are enfeebled, the internal temperature sinks, and the animal dies of protracted asphyxia. The division and other injuries of the pneumo-gastrics have no direct effect upon the production of the animal heat; they only occasion this indirectly by enfeebling the function of respiration. We have elsewhere* ad-

duced evidence to shew that these morbid changes do not necessarily follow the division of both vagi in all animals, and that the dog in a few rare cases may either die of inanition from the arrested secretion of the gastric juice and without any morbid alterations in the lungs, or may even survive the operation and recover from its effect.

Magendie, Wilson Philip,* Mr. Swan,† and Longet,‡ found that section of one vagus induced diseased action in the lung of the same side. The lesions observed by these experimenters differed very considerably in their character. Dupuytren,§ on the other hand, could discover no alteration in the lung of the side on which the vagus had been divided in two dogs and a horse, though these animals were allowed to live more than a month. In an experiment made by Magendie before his pupils, the results were completely at variance with his former expressed opinions. The right lung of a dog was found perfectly healthy, though a portion of the vagus of that side was removed six months before.‖ We have removed a portion of one vagus in seventeen animals, and allowed them to live a longer or shorter period,—from twenty-four hours to six months,—and in none of these could we detect any morbid changes in the lungs which we could attribute to the injury of the nerve. This immunity of the lung from the usual morbid changes, when one nerve only was divided, we attribute to the smaller diminution of the respiratory muscular movements, than when both nerves are divided.

Functions of the gastric branches. Do the gastric branches of the vagus contain some motiferous filaments?—Mr. Mayo¶ and Müller** failed in exciting muscular contractions in the stomach by irritating the trunks of the vagi, while this experiment succeeded in the hands of Bichat,†† Tiedemann and Gmelin,‡‡ and Longet.§§ Breschet and Milne Edwards‖‖ inferred that muscular movements can be excited in the stomach of a living animal by galvanizing the lower end of the divided vagi in the neck from its effects upon the digestive process. We have carefully and repeatedly performed the experiment of irritating the vagi, and are confident that though it occasionally fails, yet it often succeeds.¶¶ These muscular movements in the stomach differ considerably from those in the œsophagus. They are more slow and are vermicular. They generally commence at the cardiac orifice and proceed to a greater or less extent towards the pyloric orifice. Longet thinks that he can explain this discrepancy in the results of this experiment, as he found that it succeeded when the stomach was engaged in the process of chymification, and failed when it was empty. Though we are satisfied that the gastric branches of the vagus contain some motor filaments, yet we do not believe with Breschet and Milne Edwards, Brachet, Longet, and others, that the muscular movments of the stomach depend entirely upon the integrity of the vagi. Magendie* observed these muscular movements continue after section of the vagi; and we ascertained from experiment that if a dog recovers from the first effects of the operation of cutting the vagi, the stomach can still propel the chyme onwards into the duodenum. Arnold,† from his experiments upon hens and pigeons, concludes that the contractions of the stomach are less influenced than those of the œsophagus and crop by division of the vagi. The grains taken into the stomach after this operation were found, however, to be considerably less bruised than in sound animals.

Effects of lesion of the vagi upon the sensations of hunger and satiety.—Though the sensation of hunger is referred to the stomach, yet it is evident from well established facts that this sensation is actually situated in the encephalic portion of the nervous system. This sensation is not dependent, as far as we know, upon any physical condition of the stomach itself, and in all probability arises from certain organic changes in the body, connected with the want of additional supplies of nutritious matters from without. Brachet relates two experiments to show that the sensations of hunger and satiety are arrested by section of the vagi,‡ but these are liable to certain sources of fallacy against which proper precautions were not taken. Four of seventeen dogs we experimented on, lived beyond the fifth day after the division of the vagi, and exhibited no signs of having lost the sensation of hunger; on the other hand their actions indicated that they still retained this sensation. Longet has from his experiments arrived at conclusions on this point similar to ours.§ There can be no doubt that the sensation of hunger is almost always suspended for a longer or shorter time after the division of the vagi, probably occasioned in some measure by the pain and terror attending the operation, but if the animal live for a few days the sensation of hunger may return.

Though the facts from which Brachet has arrived at the conclusion that the sensation of satiety is annihilated by the division of the vagi, do not, as we have elsewhere shown,‖ warrant this inference, yet it is probable for reasons which will occur to every one in reflecting

upon the matter that this sensation is more dependent upon the physical condition of the stomach than that of hunger. At the same time we must confess that we have ourselves obtained no very satisfactory evidence from experiment, that this sensation is annihilated by division of the vagi.

Effects of lesion of the vagi upon the function of digestion. — That section or ligature of the vagi is generally followed by vomiting,—in those animals susceptible of it,—by loathing of food and arrestment of the digestive process, has been incontrovertibly proved by numerous experimenters. That perfect digestion may occasionally take place after division of the vagi in the neck even when the cut ends are kept considerably apart, is now, we are fully convinced, sufficiently established. Leuret and Lassaigne have detailed an experiment where the process of digestion went on in a horse after division of the vagi with loss of substance.* In one of Arnemann's experiments on dogs, the digestive process must have been re-established, as the animal was killed on the 165th day after the operation of dividing both vagi.† In an experiment made by Sédillot on a dog the digestion must at least have been partially restored, as the animal lived two months and a half.‡ Sédillot also mentions that Begin kept a dog alive for a month after the division of both vagi. M. Chaumet further states that no obvious change was observed in the digestion in this dog; § and he also mentions that in some similar experiments made by himself a dog lived fourteen days and digested. In four out of seventeen dogs experimented on, we obtained sufficient evidence of the restoration of the digestive process. In these animals we had not only removed a portion of the vagi, but also of the recurrent nerves. Many experimenters, among whom we may enumerate Haller,|| Brunn,¶ De Blainville,** Dumas,†† Dupuy,‡‡ Legallois,§§ Macdonald,|||| Wilson Philip,¶¶ and Dr. Hastings,*** have never obtained evidence of the continuance of the digestion after lesion of the vagi, but such negative experiments cannot be considered as neutralizing the results of the positive experiments we have mentioned above: they only show what every physiologist who has experimented much on this subject must be obliged to confess, that the digestive process is generally arrested after section of the vagi during the short time the animal usually lives after these nerves have been tied or divided, but they can never overthrow the results derived from positive experiments, provided that these have been accurately performed and are free from all sources of fallacy.

Effects of lesion of the vagi upon the secretion of gastric juice.—We have already detailed facts sufficient to prove that the removal of a portion of both vagi does not always arrest the digestion of food, and consequently does not necessarily prevent the secretion of the gastric juice. Mayer found the chyme acid in rabbits after section of the vagi. Dieckhof and Müller state that in all their experiments performed upon geese the fluid secreted from the surface of the stomach after section of the vagi was always acid, but was less in quantity than in the sound animal.* Breschet, Milne Edwards, and Vavasseur,† Dr. Holland,‡ and Brachet,§ maintain that in their experiments the gastric juice was secreted, since the food in the stomach was more or less altered. In two experiments we ascertained that the half digested food vomited, though taken into the stomach some days after division of the vagi, permanently reddened litmus-paper; and we consider the presence of chyle in the lacteals and thoracic duct as observed in the experiment of Leuret and Lassaigne, and in three of our own experiments, as furnishing decisive evidence of the secretion of gastric juice. In one of our experiments the animal was rapidly recovering flesh and strength when he was killed three weeks after division of the vagi and recurrents with loss of substance. Arnold, in his experiments upon hens and pigeons, ascertained that the fluid secreted from the stomach was acid, that it was not perceptibly diminished in quantity, and that it was capable of converting the food into chyme.||. Longet, in his experiments upon quadrupeds, found that the fluid secreted from the stomach coagulated milk and reddened turnsol paper. He further states, that the quantity of gastric juice secreted appeared to him to be greater than in the sound animal.¶ In a great number of experiments, more especially if the animal survive the operation a short time only, the secretion of gastric juice is temporarily suspended, and this enables us to explain the frequent occurrence of negative results in such researches.

Effects of lesion of the vagi upon the secretion of mucus from the inner surface of the stomach and intestines.—Sir B. Brodie relates from experiments in which animals were poisoned by arsenic where the usual watery and

mucous secretions were not poured out from the mucous surface of the stomach and intestines, though it presented the inflammation usual in such cases.* We have carefully repeated these experiments, and obtained different results. The quantity of watery and mucous secretions was nearly the same in animals after the vagi had been divided, as in animals upon which this operation had not been performed.† These experiments upon the effects of lesion of the vagi upon the different secretions poured out from the inner surface of the digestive canal, though they do not prove that the function of secretion is independent of the nervous system, seeing that numerous filaments of the sympathetic nerve are also distributed there, are yet sufficient to neutralize the evidence drawn from the effects of lesion of the vagi upon these secretions adduced by those who maintain that secretion is dependent upon the nervous system.

Effects of lesion of the vagi upon the rapidity of absorption from the inner surface of the stomach.—It has been stated by Dupuy‡ and Brachet, that the most active poisons introduced into the stomach after division of the vagi in much larger quantities than usual, produce their effects much more slowly. On the other hand Müller mentions that in thirty experiments on Mammalia performed under his direction by M. Wernscheidt, "not the least difference could be perceived in the action of narcotic poisons introduced into the stomach, whether the nervus vagus had been divided on both sides or not, provided the animals were of the same species and size."§ We have made several comparative experiments on this point,‖ and obtained results which agreed nearly with those mentioned by Müller.

The following short summary contains the principal conclusions founded upon the facts and observations above detailed, at which we have arrived regarding the functions of the nervus vagus.

1. Though the trunk of the nervus vagus at its attachment to the encephalon principally consists of sensiferous and incident filaments, it yet contains a few motor filaments. The motor filaments contained in some of the branches of the vagus chiefly come from the spinal accessory.

2. The filaments of the *auricular branch* of the vagus are sensiferous and incident.

2. The *pharyngeal branches* of the vagus are principally if not entirely motor, and move the muscles of the pharynx and soft palate in obedience to certain impressions made upon the incident filaments of the glosso-pharyngeal and fifth pair of nerves distributed upon the mucous surface of these organs.

4. The *superior laryngeal* branch is chiefly composed of sensiferous and incident filaments which are abundantly distributed upon the mucous surface of the larynx, and much more sparingly upon the inner surface of the lower part of the pharynx. The few motor filaments contained in the superior laryngeal are distributed in, and move the crico-thyroid muscle. When the superior laryngeal branches are divided or tied, every excitation of the inner surface of the larynx fails to excite sensation, or any reflex and muscular movement, and the two crico-thyroid muscles are paralysed.

5. The *inferior laryngeal* or *recurrent branch* is ramified in, and regulates the movements of all the muscles attached to the arytenoid cartilages, viz. the *crico-arytenoideus posticus* and *lateralis*, the *thyro-arytenoideus*, and the *arytenoidei*. The inferior laryngeal also furnish the sensiferous filaments to the upper part of the trachea, a few to the mucous surface of the larynx, and still fewer to the pharynx. The sensiferous filaments of the inferior laryngeal are, however, few in number and do not impart much sensibility to the parts in which they are distributed, presenting a striking contrast in this respect to the superior laryngeal. When the inferior laryngeal is cut or tied, the muscles attached to the arytenoid cartilages are no longer moved voluntarily as in speech, or involuntarily as in the muscular movements of respiration; and the arytenoid cartilages may be mechanically carried inwards by the currents of air rushing into the lungs, so as to shut up the superior aperture of the larynx and produce suffocation. When any excitation is applied to the inner surface of the larynx in the healthy state, this does not produce the contraction of the muscles which approximate the arytenoid cartilages by acting directly upon them through the mucous membrane; but this muscular contraction is effected indirectly and by a reflex action, in the performance of which the superior laryngeal acts as the incident or afferent nerve, and the inferior laryngeal as the motor or efferent nerve. It is also probable that these filaments of the inferior laryngeal distributed in the muscular fibres of the trachea are motor. The inferior laryngeal branch is the principal nerve of phonation, and when paralysed the voice becomes very faint. The effects of the paralysis of the *superior* laryngeal upon the voice are much less marked and are much more doubtful.

5. The *œsophageal branches* of the vagus are partly afferent and partly efferent nerves. In some animals, as in the rabbit, the section of the vagi in the neck is followed by the suspension of the movements of the œsophagus during deglutition, and the food is no longer conveyed along it in the usual manner. This lesion of the vagi does not produce these effects by destroying the contractility of the muscular fibres of the œsophagus, but by breaking the continuity of the nervous circle necessary for the accomplishment of all reflex movements. In some other animals, as in the dog, the food is still propelled along the œsophagus after section of the vagi, so that it is probable that in these animals the muscular fibres of the œsophagus are also called into contraction by direct excitation.

¶ Opus cit. vol. li.

6. The *cardiac branches of the vagus* have no direct effect in maintaining the movements of the heart. Though the movements of the heart may be materially influenced by causes acting through the vagus, yet mental emotions and injuries of the central organs of the nervous system affect the heart's action through the sympathetic after the vagi and recurrents have been divided in the neck.

7. The *pulmonary branches* of the vagus consist chiefly of incident filaments and convey impressions, capable of producing respiratory muscular movements, made on the inner surface of the lungs to the medulla oblongata. When the vagi are cut or tied in the neck the respirations instantly fall in frequency, and are reduced to about one half their former number. The existence of motor filaments in these branches has not yet been satisfactorily established.

8. Though excitation of the nervus vagus in the neck causes muscular contractions of the stomach, yet the muscular movements of the stomach are not entirely dependent upon the gastric branches of the vagus, and the stomach may still propel the chyme into the duodenum after the vagi and recurrents have been divided. Lesion of the gastric branches of the vagus does not necessarily arrest the secretion of the usual fluids poured out into the interior of the stomach, though these are generally changed to a considerable extent both in quantity and quality by causes acting through the nervous system. The rapidity of the absorption of poisonous substances from the inner surface of the stomach is not perceptibly diminished by the division of the vagi.

9. Division or ligature of the vagi in the neck is almost always fatal. The cause of death, in by far the greater number of cases, is congestion of the lungs with blood induced by the diminished frequency of the respiratory muscular movements. In a few cases the animal dies of inanition from derangement of the functions of the stomach.*

(John Reid.)

PAROTID REGION.—This region (in surgical anatomy) is of a somewhat pyramidal form, the base corresponding to the surface of the skin, and the apex to the pharynx. The superficial boundaries of the region are, *superiorly*, the root of the zygoma and the articulation of the jaw; *inferiorly*, a line drawn from the angle of the jaw to the anterior border of the sterno-mastoid muscle; *anteriorly*, the posterior border of the masseter muscle; and *posteriorly*, the meatus auditorius, the mastoid process with the anterior border of the sterno-mastoid muscle.

In the present article it is intended to give the relative anatomy of the parts contained in this irregular and ill-defined region.

Commencing the dissection by removing the integument from the parotid region, we expose some delicate muscular fibres which constitute the upper part of the platysma or the risorius Santorini; these fibres, however, are not constantly present. After removing a fine reticular tissue, the superficial surface of the *parotid fascia* is seen. This is a strong fibrous fascia which is continuous below with the cervical fascia; it passes over the superficial surfaces of the parotid, being attached above to the zygoma, and behind to the cartilage of the ear, while in front it is thinner and is prolonged over the masseteric region. The fascia also dips down into the substance of the gland and divides it into lobes and lobules.

The *Parotid Gland*, from which the name of this region is derived, is the largest of the three salivary glands. Its form is irregular, and is determined by the surrounding parts into the interstices of which it is packed and moulded.

Relations of the parotid.—A description of the relations of the parotid gland will include the greater part of the relative anatomy of the parotid region. The *external surface* or *base* of the gland corresponds to the skin; it is of a somewhat irregular quadrilateral form, and its boundaries are identical with those of the parotid region, except that a portion of the gland, the *socia parotidis*, is prolonged forwards with the duct over the masseter muscle. The *anterior surface* of the parotid is grooved to receive the posterior border of the ramus of the jaw; it also corresponds to the internal pterygoid muscle, the stylo-maxillary ligament, and the masseter muscle, upon the external surface of which it is prolonged, but separated from it by some loose cellular tissue, by branches of the portio dura nerve, and by the transverse facial artery. The *posterior surface* corresponds to the cartilaginous portion of the external meatus, upon the convexity of which it is moulded, and to which it is connected by dense cellular tissue; this surface is also related to the mastoid process and to the sterno-mastoid and digastric muscles. It is related *superiorly* to the zygoma and the tempero-maxillary articulation; *inferiorly* it fills up the space between the angle of the jaw and the anterior border of the sterno-mastoid muscle. It here comes into relation with the submaxillary gland, but is separated from it by the stylo-maxillary ligament. The *internal* or *deep surface* of the parotid is very uneven; it fills up the posterior part of the glenoid cavity and the space between the ear and ramus of the jaw; it surrounds the styloid process and the muscles

which arise from it, and passes down between the styloid process and the pterygoid muscles, so as to come in contact with the pharynx and the internal carotid artery, as well as the internal jugular vein, and the eighth, ninth, and sympathetic nerves. A portion of the gland passes with the internal maxillary artery between the ramus of the jaw and the internal lateral ligament; it here comes into contact with the inferior maxillary nerve, and sometimes reaches the space between the external and internal pterygoid muscles.

In addition to the relations here pointed out to the parts by which it is surrounded and limited, the parotid has important relations to vessels and nerves which pass through its substance or are deeply imbedded within and beneath it.

Arteries.—The *external carotid artery* passes into the lower border of the gland near its deep surface; as it ascends it becomes more superficial, and is continued upwards under the name of the *superficial temporal*, which passes up between the ear and the articulation of the jaw, crosses over the zygoma, and so emerges from beneath the parotid gland and its fascia.

The *internal maxillary artery* passes off from the carotid at right angles. At its origin it is imbedded in the substance of the parotid, and is nearly on a level with the lower extremity of the lobe of the ear; it bends downwards and inwards, and escapes from the parotid by passing between the ramus of the jaw and its internal lateral ligament.

The *transversalis faciei* arises from the carotid or from the superficial temporal artery at a variable distance between the angle and neck of the jaw. Its origin is imbedded in the substance of the parotid; it then goes upwards and forwards, and passes out beneath the anterior border of the gland, lying between it and the masseter muscle.

The *posterior auricular artery* is a small branch of uncertain origin. When regular it arises from the external carotid, above the digastric and stylo-hyoid muscles, opposite the point of the styloid process; it is here partly concealed by the parotid gland, in the posterior part of which it is imbedded; it then passes upwards and backwards between the ear and the mastoid process. While this artery is imbedded in the parotid it sends off a small *stylo-mastoid* branch, which passes upwards to enter the stylo-mastoid foramen. In addition to the above-mentioned arteries there are several branches variable in their number, size, and situation, which pass off from the carotid and its branches and are distributed to the substance of the parotid gland.

Veins.—The veins corresponding to the terminal branches of the external carotid artery accompany the arteries and are consequently imbedded in the parotid gland. The temporal and internal maxillary veins unite and form a common trunk, which lies superficial to the external carotid artery. This common trunk receives the posterior auricular and the transverse facial veins, as well as some veins from the substance of the parotid, and so the commencement of the external jugular vein is formed. There is also a communicating branch which passes through the parotid gland from the internal to the external jugular vein; this branch may be looked upon as one of the origins, and in some cases it is the chief origin of the external jugular vein.

Nerves.—We have next to study the relations of the nerves which are found in the parotid region.

The nerve which lies most superficially in this region is the *great auricular*, some small branches of which lie superficial to the parotid fascia and are distributed to the skin of the parotid region, while other branches pierce the fascia, and pass through the parotid in a direction forwards and upwards to be distributed on the skin of the cheek. The nerve then sends off two branches, the superficial auricular and the deep auricular.

The *superficial auricular* branch of the great auricular nerve passing vertically upwards in the dense fibrous tissue which connects the parotid with the skin, reaches the inferior part of the concha, and is distributed to the skin of the ear.

The *deep auricular* branch passes through the substance of the parotid, to place itself in front of the mastoid process, crossing at an acute angle the auricular branch of the facial nerve, which is deeper than it, and with which it anastomoses by a branch of considerable size. The nerve then passes backwards and divides into branches which are distributed to the external ear, and to the skin over the occipital region.

The *auriculo-temporal* nerve arises from the trunk of the superior maxillary by two portions, between which passes occasionally the middle meningeal artery. It passes backwards beneath the external pterygoid muscle, and between the internal lateral ligament and neck of the jaw; it then divides into two branches, a superficial or temporal and a deep or auricular branch. The *superficial temporal* passes up between the ear and the articulation of the jaw, crossing the root of the zygoma, and becoming superficial above the parotid gland; it then supplies the skin of the temple and side of the head. In its course this nerve sends off one or two branches which communicate with the portio dura nerve; it also sends branches to the tempero-maxillary articulation and to the external auditory meatus. The *auricular* branch forms a plexus behind the neck of the jaw and around the internal maxillary artery; it then divides into several branches, some of which pass through the parotid to be distributed on the external ear, while others anastomose with branches of the cervical plexus, particularly with the great auricular nerve. One branch joins the dental nerve just before it enters the dental canal, and another passes into the tempero-maxillary articulation.

The *portio dura* nerve passes out of the stylo-mastoid foramen and enters the substance of the parotid gland. At its exit from the foramen the nerve sends off three small branches, the posterior auricular, the digastric, and the stylo-hyoid.

The *posterior auricular* nerve passes off from the anterior part of the portio dura; it passes upwards and forwards round the anterior surface of the mastoid process, and is joined by the great auricular nerve of the cervical plexus; it then becomes superficial, accompanies the artery of the same name, and is distributed to the ear and side of the head.

The *digastric* nerve passes backwards and is distributed by several filaments to the posterior belly of the digastric muscle. It sends an anastomotic filament to the glosso-pharyngeal nerve.

The *stylo-hyoid* nerve arises often from a common trunk with the preceding; it enters the stylo-hyoid muscle after passing along its superior border.

After the portio dura has given off the above-mentioned branches it passes forwards through the substance of the parotid gland below the meatus auditorius externus; it then crosses over the posterior auricular artery and the styloid process, the external jugular vein and the external carotid artery, and before reaching the ramus of the jaw it divides into two branches, the tempero-facial and the cervico-facial, which diverge from each other.

The *tempero-facial division* passes upwards and forwards in the substance of the parotid, forming with the trunk of the facial nerve an arch, the concavity of which is above; it then crosses the neck of the lower jaw and receives at this point one and sometimes two branches from the auriculo-temporal branch of the inferior maxillary nerve. The tempero-facial nerve then breaks up into a number of branches which anastomose and form arches, from the convexities of which proceed a number of diverging filaments, some of which pass upwards and others forwards, emerging from beneath the parotid, to be distributed to the muscles of the face.

The *cervico-facial division* is smaller than the preceding; it takes the same direction as the trunk of the nerve, passing downwards and forwards in the substance of the parotid; at the angle of the jaw it divides into three or four branches; these subdivide into secondary branches, some of which pass forwards to supply the muscles of the lower part of the face, while others are distributed to the upper part of the cervical region.

Lymphatic glands.—Several lymphatic glands are found imbedded in the superficial surface, and in the substance of the parotid. These may readily be distinguished from the tissue of the parotid by their red colour. They are not uncommonly the seat of disease, and if their removal becomes necessary the operation may be done without much difficulty and without great risk of wounding any important textures. But a slight consideration of the deep connexions of the parotid and of its close relations to the many important parts which pass through it, and by which it is surrounded, will be sufficient to convince the surgeon that the removal of this gland cannot be effected without extreme difficulty and danger, and that it must necessarily be attended by injury to some of the important parts in this region. The division of the facial nerve, and consequent palsy of the face, may be looked upon as one of the most serious and certain consequences of an attempt to excise the parotid.

(George Johnson.)

PARTURITION, MECHANISM OF.

Parturition is the act in which the matured fruit of healthy conception and gestation is transmitted along the passages of the mother. "Rien de plus curieux que le méchanisme par lequel le fœtus est expulsé; tout s'y passe avec une précision admirable," is the quotation which the celebrated Naegelé has used for a heading to his essay on this important process in the human subject, the first in which it has been completely and accurately described. Perhaps in no department of physiology do we gain so much instruction from comparative anatomy as here; when we examine the ovipara, especially the higher orders of them, we are struck with the simplicity of the parturient process, and with the equally simple laws by which it is governed. The oval form of the egg shows that its long diameter must run parallel with the canal through which it has to pass, and in these classes of animals this single law constitutes nearly the whole mechanism of parturition in them.

In the vivipara the process becomes somewhat more complicated; the fœtus enveloped in its soft and fluctuating bag of membranes and the more perfect pelvis bring many other relations into play which do not exist in the lower classes; hence in the viviparous animals we see that the manner in which the fœtus advances through the passages of the mother varies considerably, still however not so much as to render it incompatible with the law above mentioned.

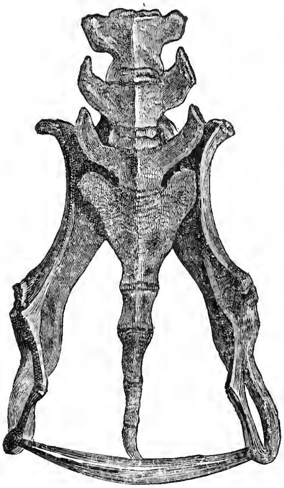
In considering the process of parturition in the lower classes of animals it will be scarcely necessary to go beyond the Vertebrata, for in the lowest classes, especially the zoophytes, it admits of but little comparison with them, the analogy rather inclining in the contrary direction, viz. towards the vegetable kingdom. In some of the other classes, viz. Vermes, &c., little certain is known as to this process beyond that the generative organs are of the simple tubular character; we must except, however, the Insecta, in many of which the ova and the mode of their expulsion strongly resemble a much higher class, viz. the Aves.

The Fishes, which are the lowest class of the Vertebrata, have no bony canal or pelvis; the whole apparatus for parturition is a tube the lower part of which at least is fibrous; in the larger fishes it is muscular and capable of considerable dilatation. In the Ray and Shark tribe we first see this canal divided into two parts, viz. the ovary and oviduct; still the process is of the simplest character, the ova being propelled precisely like the contents of an intestinal tube. In the viviparous sharks, the Blennius viviparus, and still more remarkably in the Cetacea, where as belonging to the Mammalia we first see the oviduct divided into a tube and uterus, and where the fœtus is generally so large, the parturient process is equally simple, the uterus and vagina being converted by gradual dilatation into a simple continuous canal. In the higher classes of Reptilia we first perceive a regularly formed pelvis, viz. in the Sauria, and still more completely in the Chelonia, the pelvis in the latter being considerably advanced in point of developement, even as compared with the higher Mammalia; indeed as regards pelvic developement these two classes of the Reptilia ought rather to be placed above the Aves, in whom, with one exception, the pelvis is much more imperfect. The rudimental trace of a pelvis which is seen in certain of the fishes is evidently a modification of a scapula, and intended as part of the apparatus for propulsion, being connected with the ventral fin. In the Cetacea this is marked by the existence of two small thin flat bones imbedded in muscle on each side the vent. In Birds this formation is still more marked, and here we first see distinctly the analogy pointed out by Meckel between the attachments to the trunk of the upper and lower extremities, the ilium corresponding to the scapula, the ischium to the coracoid process, and the pubic bone to the clavicle; the pelvis in them presents the transition from the scapulary bones of the lower extremities, if we may so call them, in some of the fish tribe, to the completely formed bony canal of the higher Mammalia. The pelvic bones in Birds are still subservient to little else than the purposes of locomotion, the ossa pubis not uniting in front, their points terminating at a considerable distance from each other, but connected by a ligamentous band which is elastic and capable of considerable dilatation; the process of parturition here is as simple as in the inferior classes, the egg passing along the cloaca through the half bony, half fibrous canal of the pelvis. One solitary instance of a perfect pelvis presents itself among the Aves, viz. in the ostrich, and where the symphysis pubis does not seem capable of much dilatation, although from the size of the egg there can be but little room to spare in the pelvis during its expulsion; an apparent approach to this formation is occasionally seen in birds which attain a considerable age from the deposition of bony matter into the pubic ligament. An equally solitary example of an imperfect pelvis among the Mammalia is furnished by the lesser ant-eater, the pubic bones not being united.

The lowest grade of parturition which (excepting the Cetacea) is observed in the Mammalia, is seen in certain Insectivora, viz. the mole, shrew, &c. in which this process is akin to that in those animals which either have no pelvis at all, or have them of a very imperfect kind. In the mole, &c. the pelvic cavity is so small as to be utterly useless for the purposes of parturition, not even containing the rectum, which, together with the vagina, passes down in front of the pelvis. In this instance, therefore, we have once more a strong analogy to parturition in the lower ovipara, especially as in the above-mentioned animals the uterus is still at a low grade of formation, being cylindrical and scarcely to be distinguished from its Fallopian tube.

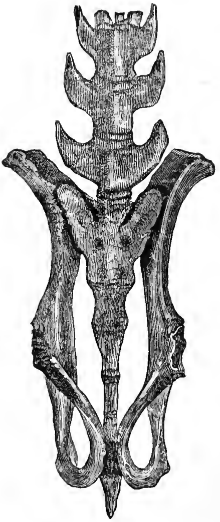
A still further advance towards the perfect pelvis is seen in the Guinea-pig, an animal in

Fig. 487.



Pelvis of the Guinea Pig at the time of parturition.

Fig. 488.



Pelvis of the Guinea Pig 72 hours after parturition.

which the fœtus attains a size utterly incompatible to pass through the small pelvis of the mother were it not for the extraordinary elasticity of the pubic ligament, being capable of allowing the ends of the pubic bones to diverge from each other to the distance of nearly an inch and a half. The capability of the pelvis being enlarged by this mechanism depends upon the shortness of its transverse, and the great length of its antero-posterior or sacro-pubal diameter, the ossa innominata running forwards from each side of the sacrum in a nearly parallel direction, or rather forming an isoskeles triangle, its apex at the pubes, its base at the sacrum. This greater length of the antero-posterior to that of the transverse diameter may be traced with few exceptions along the whole chain of *pelviferous* vertebrata until we reach the human subject, and even here, until the age of puberty, we find a similar relation between these diameters. This form of pelvis is eminently adapted for dilatation during parturition; the ossa innominata, moving, as it were, upon a hinge at their sacro-iliac synchondroses, are capable of a considerable separation at their pubic ends, by which means the pelvis is greatly enlarged and passage of the fœtus much facilitated.

In some animals, as cows, the swelling and softening of the ligamento-cartilaginous unions is distinctly seen on the approach of labour, the lumbar vertebræ and sacrum sinking between the ilia, and these bones "slipping," as it is called, over each other at their sacro-iliac symphyses as the animal moves her hind legs.

The axis of the pelvis in animals being with few exceptions parallel with the spine, and the outlet from the formation of the sacrum being so large, it will be seen that up to the Ruminantia the mechanism of parturition is extremely simple, the more so as until we reach this class the uterus in great measure preserves its tubular formation, rendering it next to impossible that the fœtus should come in any other direction than with its long diameter corresponding to the axis of the canal through which it has to pass.

In the Marsupiata the fœtus is expelled at so early a stage of developement, and is therefore so small, that little or no dilatation of the pelvis is required; in these animals we see the pelvis well developed, and the difference between the length of the transverse and antero-posterior diameters inconsiderable: in them it is probable that little or no separation of the pubic bones takes place during parturition.

In the other and higher classes of the Mammalia the hard and well developed head of the fœtus and its inflexible limbs, especially in the Ruminantia, as also the horse, ass, &c., present very considerable obstructions to its passage through the pelvis, and require that it should take a certain position during labour in order that it may be born with such a degree of facility and within such a period of time as shall not endanger its own life or that of its mother.

Although the pelvis among the higher Mammalia still presents many remarkable points of difference from that of the human race, least perhaps in the Quadrumana, still on the other hand the mechanism of parturition in these animals resembles in many respects this process in man. The embryo has a somewhat similar position in the uterus as it has in the human subject. In the early periods of pregnancy in both cases, the limbs stand off from the trunk, whereas in the latter months they are pressed close to the body. The lower extremities or hind legs in animals are always turned upon the abdomen; in some instances the knees are bent, in others not.

The arms of the child are crossed upon the breast; in animals the forelegs are usually placed along the side of the head and generally a little below it; it is rare that one or both are found above the head, although it has sometimes occurred that the two forelegs have been found crossing each other over the head. The forelegs are seldom found bent down *under* the abdomen.

The embryo usually lies upon its belly, or on one side; and from being scarcely ever found upon the back it may be presumed that this position is very rare.* The head is mostly turned towards the os uteri, although cases are by no means uncommon, even among the larger animals, of its being turned to the fundus uteri. In the larger animals (mare, cow, sheep, goat, &c.) the embryo at first lies tolerably unconstrained, whereas at a later period it descends into the smaller part of the uterus, and hence at this time we usually find the nose bent down upon the breast. In the child this position with the chin upon the breast exists from a very early period.

In the smaller animals, viz. the dog, cat, rat, &c., the head at the end of pregnancy mostly lies flat on the lower jaw, and therefore presents with the nose, whereas in the larger animals the occiput presents, and this probably withdraws again as labour comes on. The ears are always pressed close to the head, being turned either forwards or backwards; they are usually found bent forwards in the dog, cat, and horse, and backwards in the cow, sheep, goat, rabbit, hare, &c.

Although the human fœtus usually presents also with the head, the whole mechanism of its parturition is very different from that of the animals above-mentioned; the angles of the pelvic axes with the spine and with each other, and the relative size of the antero-posterior and transverse diameters, are so different that we find the greater part of the process subservient to laws which do not exist in the lower animals; nevertheless the grand primary law with which we commenced holds equally good in the human subject as in the lowest ovipara, and upon this depends the great distinction between natural and unnatural presentations; for so long as the long diameter of the child is parallel with the axis of the passage through which it comes, the child will present with its cephalic or its pelvic extremity, and can be born in that position; whereas if its long diameter does not correspond with that of the axis of the pelvis,

* Joerg.

the child lies across and presents with the arm or shoulder, a position in which it cannot be born. The two first are therefore called *natural*, the last *unnatural* presentations. In the human subject neither the antero-posterior nor the transverse are the longest, but the oblique diameters, both of the brim cavity and outlet of the pelvis, and it is only in the directions of these diameters that the pelvis is of a tolerably uniform size throughout. They are named the right and left oblique diameters according to that sacro-iliac synchondrosis from which they are drawn.

The great peculiarity in the mechanism of human parturition is that in either of the *natural* presentations the presenting part enters the pelvis *obliquely*, not only as to the transverse diameter, but as to the axis of its brim; it passes through the cavity and outlet nearly in the same position; so that it not only takes that direction in which the pelvis is most roomy, viz. in the oblique diameters, but in which it will *itself* occupy the least possible space. Having stated this law, it will now be necessary to describe these presentations of the child in illustration of it.

The cephalic end of the child may present in two ways, either with the head or the face; the former is by far the most common; it is also the most favourable for mother and child, and at one time was looked upon as the only natural and favourable presentation. The head presents either with the right or left parietal protuberance, the sagittal suture running parallel with the right or left oblique diameters, and in both cases, at the beginning of labour, crossing the os uteri.

These three facts at once confirm the law above mentioned, viz. that the head enters the pelvis *obliquely* both as to its long and perpendicular diameters, or, as before expressed, *obliquely* as to the transverse diameter and axis of the brim; for if (as is well known to be the case) the os uteri at the beginning of labour is situated at the upper part of the hollow of the sacrum, the vertex of the head will be turned towards this part of the pelvis, and the parietal protuberance being that part which is lowest and in the centre of the pelvis, it follows that the perpendicular diameter of the head will run obliquely upwards and forwards with the axis of the brim.

The first position, viz. where the right parietal protuberance presents, and the sagittal suture corresponds to the right oblique diameter of the pelvis, is known by the posterior or small fontanelle being felt in the vicinity of the left foramen ovale, the anterior or large fontanelle in the opposite direction near the right sacro-iliac synchondrosis: this has been called the first position from occurring more frequently than the other, viz. in the proportion of five to two. As the head approaches the pelvic outlet, the occiput turns somewhat more forwards, so that instead of the protuberance, the posterior and superior quarter of the right parietal bone presents: this is the part of the head which the finger at this period of labour first touches upon during examination, which first passes under the pubic arch, and first distends the os externum; the position of the head is nevertheless still oblique, for the right branch of the lambdoidal suture will be felt parallel with the left descending ramus of the pubic arch. In still further proof of what has now been stated, we may mention, that if the head be some time in its passage through the vagina, it becomes so tightly encircled by it as to produce a considerable obstruction to the circulation in the scalp; hence we shall feel a tumefaction of the cranial integuments on that part of it which presents. On examining, therefore, the head of a new-born child which has presented in the first position, it has a circular swelling of the scalp situated upon the posterior and superior quarter of the right parietal bone. This is the *caput succedaneum*, the Vorkopf of the German authors, and, as was pointed out by the late Professor Chaussier of Paris, is a distinct evidence of the manner in which the child has presented during labour. The shoulders enter the pelvis in the contrary oblique diameter to what the head does, so that if the head in the first position has passed through with its long diameter corresponding to the right oblique diameter of the pelvis, the shoulders will be found in the left oblique diameter—from this circumstance, after the head is born, the face is turned backwards and to the right.

The *second position* of the head is the reverse of the first. The left parietal protuberance presents. During the descent of the head through the brim into the cavity of the pelvis, the sagittal suture is in the right oblique diameter as in the first position, only now the posterior fontanelle is directed towards the right sacro-iliac symphysis, the anterior one to the left foramen ovale. The head descends in this position until it approaches the pelvic outlet, when it makes the quarter of a turn and passes from the right into the left oblique diameter, the anterior fontanelle now corresponding to the left sacro-iliac symphysis, the posterior one to the right foramen ovale. As the head enters the vagina and begins to pass under the pubic arch, it is the posterior and superior quarter of the left parietal bone which now presents, and upon which the puffy swelling of the scalp is situated; as in the first position it was the right lambdoidal suture which corresponded to the left branch of the pubic arch, so here it is the reverse, the left lambdoidal suture at this moment will be found parallel with the right branch of the pubic arch; in like manner, the face when born turns backwards and to the left. This change in the position of the head from one oblique diameter to the other is not peculiar to the second position, for we meet with it occasionally in the first, the anterior fontanelle being turned to the right foramen ovale, the posterior one towards the left sacro-iliac synchondrosis, the change in this case usually taking place at a much earlier period of labour than in the second position, whether it is owing to the position of the rectum or not is difficult to say. The uniformity with which this change occurs in the position of the head from one oblique diameter to the other was first pointed out by Professor Naegelé, of Heidelberg, and must be looked upon as a fact of great importance in the mechanism of parturition, second only to the discovery of the oblique position of the head by Solayres de Renhac and Matthias Saxtorph in 1771. Sometimes the head does not make the change above mentioned, but comes out with the forehead more or less forwards, the swelling of the cranial integuments being situated on the right or left frontal bone.

The face, like the head, may present in two ways, either with the right or the left side foremost. As in the head presentations the sagittal suture crosses the os uteri, so in the present instance is this the case with the ridge of the nose.

In that position which is of most frequent occurrence the chin is turned to the right side of the pelvis, the right eye and zygoma being lowest and in the middle of the pelvis; this, therefore, shows that the face, like the head, comes obliquely not only as to the transverse diameter of the pelvis, but also as to the axis of its brim. The ridge of the nose is not only the part of the face which we first are able to distinguish when the os uteri is but slightly dilated, but from its conducting the finger in one direction to the soft cushiony end of the nose, and in the other to the broad hard expanse of the forehead, it furnishes us with an excellent means of ascertaining not only that the face presents, but in what position.

As the os uteri dilates and the face advances, the chin turns towards the right foramen ovale, so that by the time it has entered the vagina, it is no longer the right eye and zygoma which form the presenting part, but the right cheek, this being now the part which the finger first touches upon during examination, precisely as in the first position of the head, it is the superior and posterior quarter of the right parietal bone; so, in like manner, it is this part of the face upon which the bruise-like swelling is situated, which it brings with it into the world. It would seem that there is a considerable analogy between the first position of the head and that of the face, and that the one can probably pass into the other; in both the right side presents, and if the head in this position swings round upon its transverse diameter, it becomes the first position of the face.

The other or second position of the face is merely the reverse of the first. The left eye and zygoma present at the beginning of labour; and as the chin, which is turned more or less to the left, moves somewhat forwards, it becomes the left cheek which first passes through the os externum, and upon which the swelling of the face is situated.

According to the best averages, we may state that face presentations occur about once in 290 labours, and from the observations of Professor Naegelé, jun., the proportion of the second position to the first is as 1.29 to 1. Beyond being now and then a little more tedious, labours where the face presents are not more unfavourable for the mother than where the head presents; for the child, however, they are not so favourable; the pressure upon the neck produces considerable cerebral engorgement, which now and then proves fatal.

The lower part or pelvic extremity of the trunk may present with the nates, the knees, or the feet; but as the former are by far the most bulky, we may bring them under the general head of *nates presentations*. In this case the child may present with the back or abdomen forwards, in either of which the transverse diameter of its pelvis runs obliquely, that ischium, which is turned forwards, being lowest in the pelvis. The position with the back of the child more or less forwards is the most common, being in the proportion of 3 to 1 of the other position. The presenting ischium advances through the os externum; the abdomen and chest follow; and the arms, which are crossed upon the breast, are usually born at the same moment. The shoulders follow in the same direction, that shoulder being first expelled which is turned more or less forwards. The head, with the chin pressed upon the breast, enters the pelvis in the opposite oblique diameter to what the shoulders did; and while the occiput rests against the symphysis pubis, the chin, followed by the rest of the face and forehead, sweep over the perineum as the head turns upon its transverse diameter from below upwards. Sometimes, although rarely, the chin is not depressed upon the breast, but the head enters the pelvis in a contrary direction, viz. with the occiput pressed into the nape of the neck, the face turned upwards, and is born in this position. Where the abdomen of the child is turned forwards, it almost invariably turns more or less backwards during the progress of the labour, either shortly after the nates are expelled, or as the thorax is advancing through the pelvic outlet.

In all these presentations, the process of labour appears to resemble, as far as possible, that in the lower classes of animals. The first stage is employed in attaining two important objects; firstly, in giving the child a natural position, viz. with its long axis parallel with that of the passage through which it has to come, and in so dilating the os uteri that the whole of it shall disappear, the uterus and vagina forming one continuous canal, exactly resembling, as far as the mechanism of the expulsion is concerned, the same process in the lower animals.

As far as we know, it is only in the human subject where it is possible for the fœtus to present across, or where its long axis does *not* correspond with that of the passage; in this case it presents with the arm or shoulder, and cannot be born in this position. This unnatural presentation chiefly arises from the contractions of the uterus in the first stage being more or less perverted or obstructed by certain causes; thus if the uterus be much distended with liquor amnii, the slight precursory contractions at the commencement of labour will have little or no effect in keeping the fœtus with its long axis parallel with that of the uterus, for the sides of the uterus are now too far separated to act upon it, and as the uterus from its distention approaches to the globular form, the child will lie just as well in one direction as in another. Moreover, when the uterus has been subject to irregular spasmodic contractions during the last week or two of pregnancy, by which its form is more or less altered, we frequently find that when labour comes on the child presents with the arm or shoulder. It is chiefly to this cause that we must attribute those remarkable cases which every now and then occur of the arm or shoulder presenting in four or five successive labours in the same individual, a fact which was first pointed out by Professor Naegelé, sen. The full-grown living fœtus can, therefore, present in only three ways, viz. with the head or face, with the nates or inferior extremities, and with the arm or shoulder. When other parts of the child present, it arises either from its having been some time dead in utero or from being premature.

(Edward Rigby.)

PELVIS.—See Supplement.

PENIS.—(*Membrum virile;* Grec. ανδρειον αιδοιον; Germ. *das Glied,* or *die Ruthe;* Fran. *verge;* Ital. *membro virile.*)

The term *penis* would appear from its derivation (*a pendendo*) to have been the popular designation of the male organ of man and of the higher animals among the Roman people. Like many other terms that we have received from our predecessors, the present has reference to a merely visual character of the organ in a small group of animals, irrespective of the important office which it is intended to fulfil in the general animal economy. At the present day, however, with a more enlarged scale of information with regard to the laws and attributes of living beings, while we retain the name, we assign to it a more comprehensive definition than its original application was intended to convey.

The penis, throughout the animal kingdom, is the organ of transmission of the male fluid to the germinal product of the female sexual apparatus; and in the mammiferous class it performs the additional office of efferent duct to the urinary secretion. In consideration of its more obvious purpose, the penis has been termed the organ of *intromission*; but this appellation, though correct in general, is incorrect in particular instances, for there are many among the inferior animals in which a rudimentary penis exists, but no intromission can possibly occur.

As generation divides its claim with nutrition in the lowest animal organisms, we are naturally led to the expectation of finding the representative of this organ among the lowest divisions of the animal scale, and this expectation is realized by research. In proceeding to this investigation, however, it cannot too strongly be impressed upon the mind, that in the lowest even as in the highest, modifications do occur which are conformable to the wants or convenience of the animals in whom they are found, without reference to any supposed gradation of developement or improvement. Thus in *Infusoria* a sexual apparatus consisting of ovary, testis, and vesiculæ seminales, has been described by Ehrenberg; and in *Rotifera* the same author has observed a contractile organ which serves to impel the seminal fluid into the oviduct. Here, then, almost on the boundary line of the animal world, is a self-impregnating animal, provided with a distinct transmittent organ by which impregnation is effected. But remarkable as this conformation may appear at first sight, examples equally wonderful become multiplied as we proceed onwards in our enquiry.

Bory St. Vincent has pointed out the existence of an intromittent spiculum in the Vinegar Eel (anguillula aceti), one of the Vibrionidæ; and Ehrenberg has observed a similar structure in another species, the Anguillula fluviatilis. Among the Cestoid *Entozoa*, which are androgynous, a distinct intromittent organ is found in Ligula and Tenia solium. In Trematoda, which are likewise androgynous, but impregnate by mutual concurrence, a penis is also met with, and is of considerable size. In Acanthocephala, the large intromittent organ of Echinorynchus gigas, the entozoon of the kidney, has been described by Cloquet; and in Nematoidea the penis has attained a size and importance which renders it a generic character. Thus the genus Filaria is distinguished from Trichocephalus by a difference in form of the preputial covering, and a similar character distinguishes Ascaris from both the preceding. Most of the smaller species of Ascaris are remarkable, from possessing a double intromittent organ, and a similar conformation is met with in Linguatula, the entozoon of the frontal sinuses of the canine race; in Cucullanus, and in Syngamus trachealis, the tracheal parasite of gallinaceous birds.

Proceeding a step higher in the animal scale we find in the class *Annelida* that the organs of generation are hermaphrodite, and so disposed as to admit of mutual impregnation. In some genera the penis is well developed and distinct, as in Planaria and Hirudo; but in others the mutual apposition of the sexes is so perfect as to render an intromittent organ unnecessary. On this principle the penis is absent in the Earth-worm. In the Leech the penis is long and slender, placed on the twenty-fourth segment of the body, while the vulva occupies the twenty-ninth.

In *Cirrhopoda*, the barnacles or acorns of the sea, the intromittent organ is well developed, and from the mode of existence of these animals and their hermaphrodite organization, may be employed as a means of self or of reciprocal impregnation.

The class *Crustacea* is composed of animals which are diœcious in their sexual organization, and whose males are provided with a distinct intromittent organ. In the lowest groups, namely, the Entomostracous Lerneæ, the penis is double; and in Decapoda and Brachiura it is temporary and formed by an eversion of the vas deferens, an adaptation of means to an end that we shall find repeated among the lower classes of Vertebrata. Throughout the whole of this class impregnation is effected by reciprocal union.

The class *Insecta* is diœcious, and an intromittent organ is a common character throughout the entire race. In some insects, as in Aphis, the penis is double, and in the greater number it is associated with special organs, termed *claspers*, which assist in the impregnating act.

The greater number of *molluscous animals* are inhabitants of the deep, and amongst them considerable diversity, as respects mode of generation, exists. Some are hermaphrodite in organisation, and self impregnating; others are hermaphrodite and mutually impregnating; a considerable proportion are diœcious, the male and female apparatus being on different individuals, and the impregnating fluid being conveyed by the medium in which they live from the male to the female animal; while some few are diœcious and impregnate by mutual concurrence. The air-breathers, or Pulmonary Mollusca, are all hermaphrodite and impregnate by reciprocal coitus. The two last alone of the preceding modes of impregnation are those in which a true intromittent organ is required; hence, although rudiments of a penis may be discovered in many Mollusca, it is only in the mutually impregnating hermaphrodites and in the concurring diœcia that it attains a size sufficiently bulky to render it an important character. Thus in the class Tunicata, which for the most part comprises self-impregnating hermaphrodites, no intromittent organ has been described. In the inhabitants of bivalve shells, which are either self-impregnating hermaphrodites, as the Oyster, or mediately impregnating diœcia, as the fresh-water Mussel, Anodonta, there is no penis. The marine Gasteropoda are diœcious; some, as the Patella, impregnating their females through the medium of the sea water by which they are surrounded, and others, including the whole of the Pectinibranchiata, impregnating immediately, being provided with a large penis for that purpose. In the genus Trochus the vas deferens terminates at the root of the penis, and the latter is grooved; and in Carniaria the intromittent organ is bifid as well as grooved. In the Pulmonary Gasteropoda, as the snails and slugs, the generative organization is hermaphrodite, impregnation being reciprocal, and the penis of very large size. Among Encephalous Mollusca, as in Pteropoda, the organisation is also hermaphrodite, and the penis of large size. In Cephalopoda, the highest class of molluscous animals, the generative structure is diœcious, but the penis is not intromittent. The penis in Sepia and Octapus is short and rudimentary, and pierced by a canal for the transmission of the seminal secretion; but in the hooked Calamary the organ is simply grooved along its under part.

In passing from the higher invertebrata to the class of *Fishes* we meet with a degradation of organization as regards the generative system. The penis, which we have seen to be properly formed for intromission in several of the invertebrate classes, is reduced to a mere papilla on the surface of the cloaca in fishes. In the Viviparous Blenny, however, in which internal impregnation takes place, the penis is larger in size, and is probably increased in length during coitus by eversion of the mucous lining of the vas deferens. In some of the higher cartilaginous Fishes it is interesting to remark that the rudimentary state of the penis is compensated for by the developement of an apparatus which seems intended to secure the contact of the cloacæ for an appreciable time. This apparatus consists of a pair of clasping organs, a provision to which we have already had occasion to advert when speaking of the generative organs of insects.

In *Amphibia*, as in Fishes, impregnation is effected by means of a close approximation, and in most instances by contact of the cloacæ. There is no penis, but as a substitute for this organ the male animal is possessed of an organisation fitted to maintain an embrace for a considerable period.

The penis of the *Ophidian* group of *Reptiles* is a true intromittent organ, and remarkable for the peculiarity of its structure. It consists of two cœcal processes, developed from the cloaca at its posterior part, and extending back into a cavity prolonged for a short distance towards the tail. These cœca are lined by a horny papillated epithelium; they are invested with a moderately thick layer of erectile tissue, and have proper muscles attached to their extremity. When the animal is excited by the venereal orgasm the turgescence of the erectile tissue causes the eversion of the cœca and their protrusion through the aperture of the cloaca. Restored to the state of repose, they are retracted by their muscles, and drawn back into their original position. In the Rattlesnake a singular modification of the intromittent organ occurs, in the bifid termination of each of the cœca. We cannot view the peculiarity of structure exhibited by Ophidia, without recalling to mind the similarly inverted disposition of the intromittent organ, which we have already seen among the Invertebrata, namely, in Arachnida.

The Lacertine *Sauria* are possessed of an inverted intromittent organ, similar to that of Ophidia. In the Crocodile, however, the penis is no longer an inverted cœcal pouch; it is grooved along its under part, attached by two crura to the pubic bones, and furnished with a rudimentary glans at its extremity. But even in the Crocodile there exists a peculiarity of structure which allies the family with the lacertine Sauria and Ophidia. The structure to which I allude, is a canal which is prolonged from the peritoneal cavity for a short distance into the substance of the penis, and there terminates by a cœcal extremity.

In *Chelonia*, the same kind of intromittent organ occurs as is found in Crocodiles, a grooved penis contained within the vestibule of the cloaca, attached to the pubic bones, and hollowed by one or more peritoneal canals. An important difference, however, is met with, when we compare the two groups of Chelonia, the marine and the land tortoises. In the former, scarcely any obstruction to impregnation results from the covering of the animal; the penis is consequently small. But in the land tortoise, where the shell extends beyond the limit of the soft parts and acts as an obstacle to intromission, the penis is remarkable for its size and length.

Among *Birds*, the penis is rudimentary in a great proportion of the class. In aquatic birds, however, it is large and constructed on the same principle as the penis of serpents, so as to be capable of eversion. In the order Anseres, the intromittent organ is remarkable for its length, and is furnished with a groove which runs spirally around its axis. In terrestrial birds, the penis is large and grooved, and provided with a ligament of elastic tissue, which effects its retraction.

Throughout the whole class of *Mammifera*, the existence of an intromittent organ, furnished with an urethral canal, is a common character. In *Monotremata*, the penis is not conspicuous externally, but is contained in a sheath distinct from the cloaca, and protrudes through the latter under the influence of excitation. In this order, moreover, we meet with the interesting condition of an urethral canal, which is intended solely for the purpose of transmitting the seminal secretion, while the urine passes away by the cloaca. In *Marsupiata*, the penis, which is of large size, is also situated in the interior of the animal in a sheath contiguous to the cloaca, but it passes through the latter when in a state of erection. Among *Rodentia*, the most remarkable character of the intromittent organ is the presence of recurved spines upon the glans penis; this apparatus reminds us of the clasping organs seen in insects and in the higher cartilaginous fishes, and is obviously intended to fulfil a similar function. The order *Edentata* affords two opposite conditions of the intromittent organ in relation to size; these conditions having reference, as in Chelonia, to the convenience of the animals. Thus in the Bradypus or Sloth, the penis is rudimentary, while in the Armadillo the organ is exceedingly large. In *Cetacea*, which from the nature of the medium in which they live, are subject to impediment in the impregnating act, the penis is enormous. In *Ruminantia* and *Pachydermata* the organ is of large size, and presents but little variety of form. In some genera it is more or less curved while in the state of repose; in others it is straight. The intromittent organ in Carnivora is rendered remarkable by the presence of a bone, the os penis, which is more or less developed in different genera. Thus in Plantigrade Carnivora it is of large size, while in the feline race it is cartilaginous and rudimentary.

In all the orders of Mammifera hitherto examined, the penis is contained either within a sheath in the interior of the body, as occurs in Monotremata, Marsupiata, and Cetacea, or in a sheath of the integument upon the exterior. But in *Quadrumana*, the transition class to man, the sheath of integument no longer exists, and the organ hangs pendent from its attachment. The os penis still remains to identify the quadrumanous race with the inferior classes, but in the higher genera, the Chimpanzée and Orang, even this character of inferior organisation is lost. Mayer,* it is true, has declared the existence of a small cartilage, of a prismoid form, and about a line or a line and a half in length, in man. This he regards as the homologue of the os penis in inferior animals. It is situated, he says, in the submucous tissue of the upper part of the urethra within the glans penis; but he finds it only in strong and powerful men. Should this observation be confirmed by succeeding research, we ought to be able to find such a structure, even more considerable in its development, in the Chimpanzée. For my own part, I am unable to corroborate Mayer's discovery, having failed in numerous examinations of the human organ instituted for the purpose of finding it.

Having thus briefly reviewed the animal kingdom in relation to the existence of an organ of transmission for the reproductive secretion of the male, and having determined the conditions under which that organ is developed and its modifications produced, we may in the next place proceed to consider the conformation and structure of the penis, taking as the proper standard of comparison the intromittent organ of man.

The penis of man is situated at the lower part of the abdomen, below and in front of the symphysis pubis, and presents some difference in character, accordant with its state of excitement or repose. In the latter condition it is cylindrical in form and hangs loosely in front of the scrotum; in the former, its shape is prismoid, with rounded edges and slightly grooved along the sides, one facet of the prism broader than the other two forming the upper surface or dorsum of the organ, and a rounded angle the inferior border. Moreover, in the state of repose, the organ makes a sudden curve in front of the pubis, the concavity of the bend looking downwards; while in the state of erection it is directed upwards, and forms a gentle curve towards the parietes of the abdomen.

For convenience of description and reference, we are wont to consider the penis as divisible into a middle portion or *body;* the upper surface of the body being called the *dorsum*, a free and rounded extremity the *glans*, and a *root* or attached extremity by which it is connected with the ramus of the ischium at each side. The length and bulk of the organ vary with the conditions of erection and repose, and also with the individual.

The anatomical constituents of the penis are, the integument and subcutaneous areolar tissue, with the fascia penis; two bodies proper to this organ, the corpus cavernosum and corpus spongiosum, mucous membrane, muscles, vessels, and nerves.

The *integument* of the penis is remarkable for the thinness and fineness of its texture, its exceeding elasticity, and generally for a deeper tint of colour than that of the surrounding skin. The tenuity of the skin is equal to that of the eyelids, but is exceeded by the integument of the scrotum, and contrasts very strongly with

* Froriep's Notizen, No. 883.

the thick and dense dermis of the neighbouring parts of the abdomen and thighs. Its colour is brown, but varies in its depth in different individuals, being darker in those of a dark complexion, and little differing from the skin of the rest of the body in persons of an opposite character. As in other parts of the body, it is well provided with sebaceous glands, but these are more numerous in that portion which invests the under part of the organ than in the dorsal region. Near to the free extremity of the penis the integument forms an ample fold, the fore-skin or prepuce *(præputium)*, which serves to envelope the glans when the organ is in repose, and to increase the investing covering when it is distended and enlarged. The prepuce is connected to the glans on its under part by means of a narrow fold termed the *frænum præputii*, and is lined by mucous membrane. Along the edge of the prepuce the mucous membrane is continuous with the skin of the penis; at the base of the prepuce it is reflected over the glans, and at the summit of the latter is continuous with the mucous membrane of the urethra through the *meatus urinarius*. Upon the under part of the glans the mucous membrane enclosing some fibrous tissue constitutes the narrow fold above described, the frænum præputii. At the base of the body of the penis, the integument is continuous with that of adjoining parts, with the skin of the pubes superiorly, and of the scrotum laterally and beneath. In this situation, moreover, it is altered in its characters; it is thicker in its texture and furnished with numerous hairs. The latter differ from the hairs of the pubes in taking the direction of the axis of the penis, and in being, unlike the former, perfectly straight. Along the inferior border of the penis the integument presents a somewhat prominent line, which is continuous with the raphé of the scrotum behind and with the frænum of the prepuce in front. This is the *raphé* of the penis, and indicates the mode of formation of the urethra, by the conjunction of two lateral segments on the middle line.

The subcutaneous areolar tissue connecting the integument to the body of the penis is extremely lax, and wholly devoid of adipose formation. The laxity of this tissue has the effect of permitting an enormous increase of size in the organ without inconvenience; thus in the state of repose the prepuce usually covers the glans either partially or completely, and protects the mucous membrane from the attrition of dress; but in the state of erection this duplication is wholly effaced, and the integument rendered tense over the entire organ. In large herniæ and in very large tumours of the scrotum again, the integument, from its extreme looseness of attachment, is withdrawn from the penis, and contributes to the investment of the swelling. In this way the whole of the integument is sometimes distended with the tumour, and the penis lies buried in the enlargement; its situation being only distinguishable by means of a valvular opening, through which the urine trickles. Like all loose cellular tissue which is indisposed to the production of fat, the cellular tissue of the penis, in a state of inflammation, is particularly liable to serous infiltration, which renders the organ swollen and œdematous.

The *fascia penis* is a thin but dense layer of white fibrous tissue, which immediately invests the penis, forming for it a kind of sheath, and is continuous with the superficial perineal fascia. On the dorsum penis the fascia covers in the dorsal vessels and nerves, and is closely connected with the aponeurosis of the erectores penis muscles; indeed it is rendered tense and stretched over the organ by the action of those muscles.

The *corpus cavernosum* forms more than two-thirds of the bulk of the penis; it is usually described as two distinct bodies under the name of corpora cavernosa, but it is more correct to consider it as a single organ divided posteriorly into two parts, and separated in the interior by an imperfect partition. Apart from the other components of the penis the corpus cavernosum represents a lengthened cylinder somewhat flattened from above downwards and grooved along the middle line both upon its upper and under surface; the upper groove lodging the dorsal vein, arteries and nerves, and the under the corpus spongiosum. Anteriorly the corpus cavernosum terminates in an oblong and rounded extremity, which is received into a depression on the posterior surface of the glans; and posteriorly it divides into two rounded and conical processes, about two inches in length, which separate from each other and are firmly inserted into the everted edge of the ramus of the ischium and pubis under the name of *crura penis*.

The corpus cavernosum is closely connected to the glans penis and corpus spongiosum by dense areolar tissue and by a few vessels of communication. Behind and inferiorly it is attached to the rami of the ischia by its two crura; and above it is connected to the symphysis pubis by means of a strong fibrous ligament of a triangular form, the *ligamentum suspensorium penis*. This ligament is inserted by one border into the fibrous structure covering the symphysis pubis, and by its base is continuous with the aponeurosis of the erectores penis muscles and with the fascia penis; the remaining border being free and directed forwards. In a few rare instances the ligamentum suspensorium penis has been found to contain some muscular fibres.

The *corpus cavernosum* is composed of a cellular structure enclosed in a thick fibrous tunic of great strength. The tunic is constructed of longitudinal fibres closely interwoven with each other so as to constitute a tissue which possesses perfect elasticity, and yields freely to distension up to a certain point, but resists enlargement beyond that limit. From the interior of this tunic are given off a number of fibrous bands and cords *(trabeculæ)* which pass in a radiated direction from the middle line of its inferior wall to the rest of the internal circumference of the cylinder, to which they are firmly attached. The trabeculæ are most abundant in the middle line of the organ, where they are extended in a vertical direction from the middle line of the inferior to the middle line of the superior wall, forming a partial septum between the two lateral halves of the corpus cavernosum. The median partition is most complete posteriorly; in front it is very deficient, and being composed of parallel fibrous cords, between which the cellular structure of the two sides of the organ communicate, has given rise to the idea from which it received its name of *septum pectiniforme*. The fibrous cords of the corpus cavernosum serve, by means of their attachment to every point of the interior of its fibrous tunic, to equalise the pressure of the circulation during erection, and prevent the undue distention of its walls. The fibrous tunic is variable in degree of thickness in different parts of its extent; thus it is thin upon the crura penis, and is thin also in the situation of the inferior groove and at its extremity; in the two latter situations it is pierced by several vessels which communicate with those of the corpus spongiosum and glans penis.

The cellular structure of the corpus cavernosum is composed of a plexus of dilated veins, which communicate with each other so freely as to represent, when divided by a section, a perfect network of cells separated from each other by membranous parietes. The areæ of these venous cells are smallest near the circumference of the corpus cavernosum, where they are separated by a greater thickness of parietes, and greatest in the centre of each lateral half, where the intervening septa are thin and membranous. The veins are lined in their interior by a continuation of the common internal coat of the veins, and the interspaces between them are occupied by contractile fibrous tissue. The contractile fibrous tissue is disposed in parallel fibres separated to unequal distances by common areolar tissue; it is most abundant in the thicker parietes of the veins of the circumference of the corpus cavernosum, and is diminished to two or three fibres in the thinner walls of the central veins. The fibres are straight in their direction, and arranged transversely with regard to the cylinder of the corpus cavernosum. Upon meeting the cylinder of a vein in their course they diverge at an acute angle, and continue their straight direction until again obstructed by another vein, when they again separate without exhibiting any tendency to converge and enclose the vein. At the point of divergence they are crossed by other fibres at the same angle, but coming in a different direction, so that the parietes between each vein are formed by numerous fibres of this tissue, crossing each other at the angles of interstice between three or four veins, but straight and parallel between every two contiguous veins. The contractile fibrous tissue is remarkably abundant in the horse, where, from the redness of its hue, it resembles muscular substance; in man it is not abundant but very distinct, and in some situations I was enabled to detect it encircling the cylinders of the veins, and forming as it were an additional coat to those vessels.

The contractile fibrous tissue of the corpus cavernosum has been made the subject of controversy between several of the physiologists of Germany, on account of its resemblance to muscular substance and the absence of other attributes of muscular fibre. It is described by Müller in the 48th number of the Medicinische Zeitung des Vereins für Heilkunde in Preussen, as a peculiar, red, fibrous substance, and in the Archiv for 1835* he speaks of it as a "substance having a fleshy muscular appearance, of a pale red colour in the penis of the horse, and also in the dog and man. It forms an irregular network of columns (Balken) distantly resembling the network and trabecular structure of the muscular columns of the heart." His next inquiry was to determine the nature of this substance. "To decide," he says, "whether a reddish fibrous tissue be muscular or otherwise, there are three modes,—the microscope, chemical re-agents, and experiment on the living body. In vivisection of the horse, dog, and ram, I saw no contraction of this substance under the influence of the galvanic current. The results of microscopic investigation in the horse are unfavourable to the opinion that it is muscular, for the fasciculi present no indication of the characteristic transverse striæ of muscular fibre, for although the transverse striæ be indistinct on the muscular fasciculi of organic life, they nevertheless exist. In stating the results of chemical investigation, I must remark that I speak solely of this peculiar substance as examined in the horse, and not of that of any other animal or of man. To render these experiments accurate and certain, it is necessary to remove from the tissue every particle of tendinous fibre which may pervade it, for this, as we shall perceive, has a very different chemical composition. In chemical characters, the substance under consideration does not belong to those tissues which afford gelatine by boiling, as is the case with tendinous, cartilaginous, and cellular tissue; for, after seven hours' boiling, I was unable to extract from the pure tissue, separated from all foreign substances, the slightest trace of gelatine. By boiling we obtain a substance precipitable by infusion of galls, which does not gelatinize, but gives off a powerful odour of osmazome. It agrees with muscular fibre and fibrine in being precipitated from a solution in acetic acid by ferro-cyanate of potash, and differs in this respect from the class to which cellular tissue, tendinous tissue, and elastic tissue belong, for these are not invariably precipitable from a solution in acetic acid by ferro-cyanate of potash. It would, however, be incorrect to deduce the conclusion that this tissue must therefore be muscular, for there exists an entire class of substances whose solution in acetic acid is precipitable by ferro-cyanate of potash, such as albumen, fibrine, muscular tissue, and corneous tissue."

* Page 28, in his report for the preceding year, in reply to a misapprehension on the part of Krause.

Krause,* having recourse to the chemical investigation of this substance in man, came to a very different conclusion from that of Müller. "After many hours boiling," he says, "the fibres of the corpus cavernosum of man are converted almost wholly into gelatine, whereas, in boiling muscular substance, the cellular substance alone suffers this change, and the muscular fibre becomes still more evident. Again, if a portion of the boiled internal structure of the corpus cavernosum, not as yet reduced to jelly, and a portion of muscular fibre boiled for an equally long time, be examined with the microscope, the difference is more apparent than in the fresh condition. A solution of the fibrous structure of the corpus cavernosum (previously well washed with water) in concentrated acetic acid is not precipitated by ferrocyanate of potash, whereas a similarly treated solution of muscular fibre affords an abundant white or blueish-white precipitate." In reply to Krause's analysis, Müller remarks: "it will be seen that our investigation on the corpus cavernosum of the horse gives a precisely opposite result to that of Krause on the same part in man; whence it follows, either that Krause has examined this peculiar substance mingled with other structures, as cellular tissue, &c., or that it does not exist in man. Had Krause investigated the tissue described by me in the penis of the horse, he would undoubtedly have met with the same results which I have so constantly obtained."

Besides the fibres of contractile fibrous tissue distributed through the parietes of the venous canals, the arteries and nerves of the corpus cavernosum also ramify in the intercellular substance in their course through the structure of the penis.

The *corpus spongiosum* (corpus cavernosum urethræ) is a lengthened cylindrical body situated along the under surface of the corpus cavernosum in its inferior groove, and forming the inferior border of the penis. It commences posteriorly between and beneath the crura of the penis by a rounded enlargement, the *bulb*, and terminates at the extremity of the organ in the *glans penis;* the intermediate portion is cylindrical in form, and enlarges gradually from its middle towards the two extremities, the bulb posteriorly and the base of the glans in front.

The glans penis resembles in form an oblique section of a cone, rounded at its apex; it is slightly compressed from above downwards, and is terminated posteriorly by a prominent border, the *corona glandis*. At the apex of the glans is a small vertical slit, the *meatus urinarius*, which is bounded by two more or less protuberant labia, and extending backwards along the middle of its under surface is a grooved raphé, to which is attached the frænum præputii. The colour of the glans penis presents a deeper tint of red than that of the neighbouring integument, and is invested by mucous membrane. At the meatus urinarius this membrane is continuous with the mucous lining of the urethra, and at the base of the glans is reflected on the inner surface of the prepuce, as far as the free margin of the latter. The corona glandis is studded by a number of small papillary projections, formed by sebaceous glands, the *glandulæ Tysoni (odoriferæ)*, which pour out a whitish, unctuous, and strongly scented secretion to lubricate the surface of the glans and prepuce. Behind the glans is a deep furrow, bounded by the corona in front, and posteriorly by the fold of the prepuce.

* Hecker's Annalen, February, 1831.

Examined with the microscope, the surface of the glans penis is found raised into small rounded papillæ which cover every part of its surface.

The corpus spongiosum is traversed in the direction of its length by the common urino-sexual canal, the urethra. At the commencement of the corpus spongiosum, the urethra occupies a groove upon the upper surface of the bulb; further on it enters the substance of the body, but lies much nearer to the upper than the lower surface, while at its termination it occupies the lower segment of the glans.

The corpus spongiosum resembles the corpus cavernosum in being composed of a plexiform vascular structure enclosed in a dense and strong fibrous investment, but it differs from that body in the smaller size of its venous canals, the thinness of its fibrous tunic, and especially in enclosing the canal of the urethra. The vascular structure of the corpus spongiosum, like that of the corpus cavernosum, consists of dilated veins of smaller size than those of the latter body, and separated in the same manner by membranous parietes. In the glans penis the veins are even smaller than in the body of the corpus spongiosum, particularly near the surface and around the embossed border of the corona glandis. The contractile fibrous tissue appears to me to be similarly distributed between the veins, but is smaller in quantity than in the corpus cavernosum. Mayer also describes this tissue as existing in the parietes of the venous canals of the corpus spongiosum, but Müller denies its existence in that body, and observes, "in the corpus spongiosum, where Mayer also admits this substance, it is not present, at least it is perfectly clear that it does not exist in that body in the horse." The fibrous tunic of the corpus spongiosum is continuous at its bulb with the anterior layer of the deep perineal fascia.

The *mucous membrane* of the penis is the lining of the urethra and the investment of the glans and internal surface of the prepuce. In the canal of the urethra, near the extremity of the organ, it is of a deep pink colour, and becomes gradually paler as it approaches the bladder. By the contraction of the coats of the urethra it is thrown into longitudinal folds; and it is furnished with numerous small lacunæ, which are especially numerous along the upper surface of the cylinder. The openings of these lacunæ are directed forwards, and are calculated to afford an impediment to the passage of any small instrument into the bladder by catching its point. One lacuna of larger size than the rest is situated in the upper wall of the urethra, at about an inch and a half from the meatus; it terminates by several ramified ducts in the submucous tissue of the canal. The mucous membrane of the urethra is separated from the tissue of the corpus spongiosum by a moderately thick fibrous layer, which is continuous with the external tunic of the spongy body.

Sir Everard Home conceived that the external tunic of the canal of the spongy portion of the urethra was muscular, and states with regard to it: "the muscular covering by which the membrane is surrounded or enclosed is made up of fasciculi of very short fibres, which appear interwoven together and to be connected by their origins and insertions with one another; they have all a longitudinal direction." "The fasciculi are united together by an elastic substance of the consistence of mucus." Sir E. Home is mistaken with regard to the muscularity of the external tunic of the spongy urethra, but his description, as it relates to the disposition of the fibrous tissue, is correct. Indeed it is evident that it is to this tissue that Sir E. Home alludes, from a subsequent passage in his essay, wherein he identifies his muscular coat with the fibrous lining of the canal of the corpus spongiosum. Thus he writes: "Immediately beneath the muscular portion of the urethra is the cellular structure of the corpus spongiosum." And this inference is still further corroborated by his belief that the external fibrous tunic of the corpus cavernosum has also "an admixture of muscular fibres."

The muscles of the penis are, the erectores penis, acceleratores urinæ, ischio-bulbosi, and compressores venæ dorsalis.

The *erector penis* (m. ischio-cavernosus) is the muscle of the corpus cavernosum. It arises by tendinous fibres from the anterior part of the tuber ischii, from the internal border of the ramus of the ischium, and from the root of the crus penis; it then curves in an oblique direction around the corpus cavernosum, and terminates partly by becoming inserted into the side of that body, and partly by a tendinous aponeurosis, which is continuous with a similar aponeurosis derived from the opposite muscle. In the first part of its course the muscle is tendinous; where it is spread out on the crus penis and corpus cavernosum it forms a thin fleshy layer, which is prolonged for about one-third along the penis, while in the rest of its extent it is again tendinous, and constitutes the thin aponeurosis above described. The erector penis appears to effect its action as an erector by compressing the crura and vena dorsalis, and is aided in this office by the connection of its aponeurosis by means of the suspensory ligament with the symphysis pubis. When called into exercise both muscles act together, and by their united action embrace the root of the penis, and strongly compress it. The effect of pressure on the vena dorsalis must obviously be to impede the return of the venous blood from the penis, and the compression of the crura produces the same result on the veins of the corpus cavernosum.

The *acceleratores urinæ* (m. bulbo-cavernosus) are the muscles of the corpus spongiosum; they are situated on the posterior third of that body, and form a thin muscular plane which surrounds its cylinder, and is spread out upon the under surface of the bulb. Each muscle arises from the posterior border of the deep perineal fascia at the middle line, and from a median raphé which is closely adherent to the under surface of the bulb and corpus spongiosum, and which connects it with its fellow of the opposite side. From this extensive origin the fibres of the muscle pass obliquely outwards and forwards, the most posterior to be inserted into the ramus of the ischium and pubis, the middle and most numerous to encircle the corpus spongiosum, and uniting by tendinous fibres with the muscle of the opposite side upon the upper surface of that body, to be inserted into the inferior groove of the corpus cavernosum; and the anterior forming a narrow fasciculus to pass outwards upon the corpus cavernosum and be inserted into its fibrous tunic and into the fascia penis. The posterior fibres are almost transverse in their direction, and cross the triangular interval between the bulb and crus penis, being separated from the deep perineal fascia by the superficial perineal vessels and nerve, and by the ischio-bulbosus muscle when it exists.

The acceleratores are well calculated to contract forcibly the canal of the urethra, and thus to communicate an expulsive impetus to the stream of urine or seminal secretion passing along the tube. The expulsive action of these muscles is made sensible to the hand when we withdraw a catheter; and the strength of its gripe, when the catheter has been lodged in the bladder. Indeed their complete contraction constitutes an impassable though temporary obstruction to the passage of the catheter along the urethra, and gives rise to that form of impediment which is known by the name of spasmodic stricture. The contraction of these muscles, moreover, acting suddenly on the urethra, serves to expel the last portions of urine and seminal secretion. Besides the influence which they exert on the urethra, the acceleratores urinæ also enact the part of erectors of the penis, by producing so much pressure on the bulb and posterior part of the corpus spongiosum as may impede the return of blood through the venæ corporis spongiosi, and at the same time press forwards the contents of the venous plexus of the bulb into the anterior part of the corpus spongiosum and glans penis; and their action in this respect is increased by the tension made by their anterior fasciculi on the fascia penis, and through it on the vena dorsalis.

The *ischio-bulbosus* (m. transversus perinei alter; m. transversus perinei profundus) is a small fan-shaped muscle situated in the triangular interspace between the bulb of the urethra and crus penis, and is not unfrequently wanting. It arises by a pointed origin from the ramus of the ischium, and passing obliquely inwards across the triangular space above described, spreads out into a thin fan-shaped plane, and is inserted into the fibrous tunic of the bulb. On one occasion I found this muscle so large that it extended forwards to the middle of the penis, and usurped the place of the accelerator urinæ, which was absent. The ischio-bulbosus muscle is separated from the transversus perinei by the folded border of the deep and superficial perineal fasciæ, and from the compressor urethræ by the anterior layer of the deep perineal fascia. It covers in the internal pudic vessels and nerve.

The action of the ischio-bulbosi muscles is to compress the bulb, and by their pressure to aid the posterior fasciculi of the acceleratores urinæ in producing turgescence of the corpus spongiosum. In the variety to which I have alluded above, the ischio-bulbosi must have performed the whole of the duty of the acceleratores.

The *compressor venæ dorsalis penis* is a small muscle, first described by Dr. Houston,* of Dublin. According to that gentleman it is found very commonly among mammiferous animals, and also in the human subject when the muscular system is well developed. To its existence in the dog and cat I can bear witness, having repeatedly prepared it for Dr. Jones Quain, who was wont to demonstrate it in his lectures; I have been less successful in the human subject, and have never obtained a satisfactory view of a distinct pair of muscles in the situation indicated by Dr. Houston. "In man," writes this author, "the compressores venæ dorsalis are less distinct than in most of the mammalia. They arise from the rami of the pubis above the origin of the erectores penis and crura, and ascending in a direction forwards are inserted above the vena dorsalis by joining with each other in the mesian line. They form a thin stratum of muscular and tendinous fibres about an inch long and three quarters of an inch broad, and may perhaps be looked upon as portions of the erectores penis, which, instead of being inserted into the sides and lower part of the corpora cavernosa, mount over those bodies to exert their compressing influence on the vena dorsalis. They enclose between these and the penis, the veins, arteries, and nerves of this region. Their anterior fibres are distinguished from those of the erectores by the fibrous attachment of the crura to the pubis; their posterior margins are kept distinct from the front part of the levatores ani, known under the name of Wilson's muscles, by the pudic artery, which divides them in its course towards the dorsum of the penis."

"The best procedure to display these muscles is the following. Detach the bladder and levator ani with the hand from one side of the pelvis; then divide with the saw the pubis and ischium about one inch from the symphysis, and break off the bones at the sacro-iliac articulation; next dissect away carefully the remaining portion of the pubis from the symphysis, periosteum, and crura penis, and then the compressores venæ, bearing still their natural relations to the crura and other muscles, may be exposed with very little difficulty. The insertion of the muscles being in a great measure outside the pelvis, they may also be demonstrated without the section of the bones, by cutting on them in front of the pubis and looking carefully for their tendon at the side of the vena dorsalis: from the tendon the knife may be carried downwards and backwards in the course of the fibres, and nearly the whole of the muscle can be thereby exposed. It must, however, be remembered that it will be needless to search for them in a thin emaciated individual, where the other muscles of the perineum are so pale and soft that even they can scarcely be distinguished. The subject should be robust, and the muscles red, in order to demonstrate them."

Respecting the action of these muscles Dr. Houston observes: "The use of the musculi compressores venæ is self-evident and cannot be mistaken; the effect of their contraction will be to close the vein and mechanically obstruct the current of blood. A simple experiment will prove to demonstration that such will be the necessary result of their contraction. Let the muscles be stretched in the natural direction of their fibres, and any fluid forced into the vein will not find a passage through the vessel beyond the spot where it is compressed by their tendon: a very gentle pull of the muscles will be sufficient to produce this effect. In cases where the vein runs through the tendon the pressure will be most efficacious, but even in those in which the tendon is arched over the vein its descent from the contraction of the muscles will sufficiently compress the delicate tunics of the vessel to produce the required effect."

The *arteries* of the penis are derived from the internal pudic, itself a branch of the internal iliac artery. They are three in number on each side; the artery of the bulb, the artery of the corpus cavernosum, and the arteria dorsalis penis.

The arteria corporis bulbosi is given off from the internal pudic at a point corresponding with the level of the urethra, and passes transversely inwards to the bulb, which it enters close to the lower part of the urethra. In its course inwards it lies along the upper border of the transverse portion of the compressor urethræ muscle, and crosses that muscle obliquely from within outwards. It is situated between the two layers of the deep perineal fascia, and is surrounded by a sheath derived from the anterior layer of the fascia as it enters the bulb. Having entered the corpus spongiosum, the artery runs forwards in the midst of the venous canals of that body to the glans penis, in which it distributes its ultimate branches. In its course the arteria bulbosi gives off numerous ramuscules, which ramify in the walls of the venous canals.

The arteria corporis cavernosi is given off from the internal pudic, somewhat nearer to the symphysis pubis than the preceding, and opposite the point of junction of the crura penis; it pierces the fibrous tunic of the crus penis on its inner side, to enter the structure of the corpus cavernosum. In the latter it

* Dublin Hospital Reports, vol. v. page 459.

runs forwards by the side of the septum pectiniforme, distributing many branches in its course, which ramify in the parietes of the venous canals.

The arteria dorsalis penis may be regarded as the continuation of the internal pudic, after the latter has given off the arteria corporis cavernosi. It commences opposite the junction of the crura penis, and piercing the anterior layer of the deep perineal fascia, ascends to the groove upon the dorsum penis. In this groove it runs forwards to the base of the glans, where it divides into several branches, which enter the substance of that body and are distributed to its structure. The arteria dorsalis is separated from its fellow by the dorsal vein, and gives off numerous branches in its course to the fibrous structure of the penis and integument.

The *veins* of the penis correspond with the arteries which they accompany in their efferent course. The *venæ corporis bulbosi* and *venæ corporis cavernosi,* issuing respectively from the bulb and crura penis, take the course of the internal pudic artery, and constitute the internal pudic veins. At the root of the penis these veins communicate with the dorsal vein.

The dorsal vein commences by numerous large branches, the chief of which issue from the base of the glans beneath the corona, and form by their communications a considerable plexus on the anterior part of the corpus cavernosum, the others being the veins of the prepuce and integument. The union of these veins constitutes two trunks of equal size, which, after running side by side for a short distance, unite and form the dorsal vein. The dorsal vein in its course towards the root of the penis passes beneath the aponeurosis of the erectores muscles, together with the attachment of the suspensory ligament, and after piercing the deep perineal fascia, divides into several branches which join the prostatic and vesical plexus. It receives in its course several large branches from the corpus spongiosum, which curve around the corpus cavernosum in order to reach it, and communicates at the root of the organ with the deep veins of the penis. The dorsal vein is situated in the middle line of the groove of the dorsum penis, having its corresponding artery at either side, and being covered in by the fascia penis and conjoined aponeurosis of the erectores penis muscles. It is this relation to the fascia penis and aponeurosis of the erectores that enables the latter to compress the vein forcibly against the dense fibrous coat of the corpus cavernosum, and thus intercept the current of venous blood.

The question of the ultimate arrangement of the bloodvessels in the substance of the penis leads to enquiry into the nature of erectile tissue, a subject to which a separate article has been devoted in the earlier pages of this work, and to which I must now refer my reader. From my own investigations into the structure of this tissue in the corpus cavernosum and corpus spongiosum, I have come to the conclusion that the arteries ramify and terminate in capillaries as in other parts of the body, and that these latter very speedily become dilated veins. In the distribution of the veins the only peculiarity of this tissue exists; these by their tortuous windings form an inextricable plexus, which fills the whole area of the fibrous tunics of the corpus cavernosum and spongiosum, and constitutes their component substance. In this plexiform aggregation of veins, the walls of the vessels so closely approach as to leave between them only so much connecting tissue as serves for the ramification of the arteries and nerves of the organ, and for the passage of the fibrous trabeculæ and fibres of the contractile tissue. It follows from this arrangement that the areæ of the veins bear a much greater proportion to the bulk of the tissue than do the septa between them, and, consequently, that if a section of the corpus cavernosum be made, its parenchyma will have the appearance of a cellular network, an appearance that is rendered much more striking when the penis has been inflated and dried. It is obviously this appearance of the parenchyma of the corpus cavernosum that has gained for it the character of being composed of cells, and in truth, as far as the plane of the section is concerned, the portions of venous canals which open on the surface have all the attributes of divided cells. According to the position of the veins at the point of section, the cell in one spot is shallow and small, in another it is lengthened, either in the longitudinal or in the transverse direction of the axis of the corpus cavernosum, and in a third, again, the apparent cell is irregular in form, from the conjunction at that point of two or more veins. If, in the next place, we turn our attention to the septa of the apparent cells, we shall meet with spots in which from the close assemblage of the veins the septum has the appearance of a star giving off a number of thin lines in a radiated direction to form partitions between three, four, or five veins which meet at that point. Now let us suppose that this observation is being made on the parenchyma of the corpus cavernosum, the arteries of which have been previously injected with fine injection. Where do we look for the injected arteries? Obviously in the septa, and especially at that thicker portion of the septum where several veins lie in contact. And what, we may ask, is the probable appearance of the arteries in that star-like point of septum which I have described above? I can answer this question, from repeated observation. It is that of a short trunk giving off two, three, or four small and short terminal branches, which diverge in an oblique direction from the extremity of the small trunk, and terminate abruptly at the cut margin of the septum. I have seen the appearances here described many times, sometimes better, sometimes less distinct, and more frequently as a bifid division than another, and these I apprehend are the *arteriæ helicinæ* of Müller. Besides the preceding, the special characters of the arteriæ helicinæ are their projection in the form of a tuft into a venous canal, and the curved, swollen, and conical form of the small branches at their extremities. The first of these appearances is due to the accidental position of the section under the microscope, so that the short trunk with its terminal twigs appears to be placed within the area of a vein projecting into it like a blossom on its stalk; the second results from the contraction of the coats of the artery, the effects of the longitudinal contraction giving rise to the curve and to the enlargement near its extremity, and the transverse contraction, by producing the expulsion of some part of the injection, to the conical form of the extremity itself. "These remarkable arteries," writes Müller,* "have a great resemblance to the tendrils of the vine, only that the arteries are much shorter in proportion to their thickness; from this resemblance I have named them arteriæ helicinæ or tendril-like arteries. We may also compare their ends to the top of a crook. By close examination with the microscope they may be seen projecting into the venous cells, not, however, bare, but covered with a fine membrane that under the object-glass looks horny."

If the description which I have here given of erectile tissue be the true one, it is clear that the arteriæ helicinæ have no existence, and that that appearance of the small vessels, to which Müller has given this name, is a necessary consequence of the natural distribution of the ordinary vessels of the organ. I may be permitted to remind my junior reader that it was through the medium of the arteriæ helicinæ that Müller supposed the venous canals of erectile tissue to be filled during erection, while, for the purposes of nutrition and maintaining the ordinary circulation of the organ, the arteries pour their blood into capillaries, and these into veins. Excepting during the moment of discharging their blood, this physiologist conceived that the small curved terminal twigs were impermeable, and that it was only under the influence of the erectile nervous function attending erection that the impetus of the arterial blood was sufficient to open the concealed apertures at their extremities.

The *lymphatic vessels* of the penis are found chiefly on its dorsum, taking the course of the dorsal vein. At the root of the organ they curve outwards to the groin, and communicate with the upper group of inguinal glands. I have frequently seen a small lymphatic gland on the dorsum penis near its root.

The *nerves* of the penis are derived from the internal pudic and from the hypogastric plexus; those from the former source are the anterior superficial perineal nerve, the nerve of the bulb, and the dorsalis penis nerve.

The anterior superficial perineal is a branch of the perineal division of the internal pudic. It enters the perineum at the posterior border of the deep perineal fascia, and passing onwards in the groove between the erector penis and accelerator urinæ, gives branches to the scrotum, and is finally distributed to the integument of the under part of the penis as far as the prepuce.

* Archiv, 1835.

The nerve of the bulb is also a branch of the perineal division of the internal pudic, and likewise enters the perineum through the posterior border of the deep perineal fascia. Between the superficial and deep fascia, and behind the transversus perinei muscle, the nerve passes obliquely forwards to the bulb, where it gives off several long and slender branches, which run forwards on the fibrous tunic of the corpus spongiosum, and then enters the bulb in company with the artery, to be distributed to the vascular parenchyma of that body and to the urethra as far as the glans penis.

The perineal division of the internal pudic nerve also gives branches to the acceleratores, erectores, and ischio-bulbosi muscles.

The dorsal nerve of the penis is the superior or deep division of the internal pudic. This nerve accompanies the internal pudic artery to the anterior part of the arch of the pubis, where it pierces the deep perineal fascia and passes onwards to the dorsum penis. In the latter situation it lies externally and somewhat superficially to the dorsal artery, and enters the base of the glans penis by several branches, to be distributed to the papillæ of that body. Near the root of the penis the dorsal nerve gives off a large branch, which passes obliquely along the side of the corpus cavernosum, and divides into numerous long and slender branches, which are distributed to the integument of the upper and lateral aspect of the penis, to the fibrous covering and substance of the corpus cavernosum, and to the prepuce. The nervi dorsales communicate with each other, on the dorsum penis, by anastomosing filaments.

The nerves derived from the hypogastric plexus are slender ramuscules, which accompany the arteries of the corpus cavernosum and bulb into the interior of the penis, and are distributed to its internal structure.

Developement.—The first indication of the developement of a penis is perceived towards the end of the fifth week after conception, at which time it exists in the form of a slight prominence, situated immediately in front of the common urino-sexual aperture. By the seventh or eighth week this prominence assumes the lengthened character of the future organ, and is grooved along its under side, the groove being an extension of the common urino-sexual cleft. The glans penis makes its appearance during the ninth week, and the urinary groove is continued beneath it. During the tenth and eleventh weeks the urinary groove becomes separated from the anus by the growth of a transverse septum, and the borders of the groove begin to lengthen and coalesce on the median line, in order to form the urethra. This process commences from behind, and proceeds forwards towards the glans, attaining its completion at about the fifteenth or sixteenth week. When it remains imperfect from arrest of developement, it constitutes that form of deficiency which is termed Hypospadias. The prepuce is developed at the same time with the closure of the urethra.

(*Erasmus Wilson.*)

PERICARDIUM.—See Heart.

PERINEUM (in Surgical Anatomy).—The perineum (in the general acceptation of that term) is one of the names applied by anatomists to the extensive region which contains the lower part of the rectum intestine, together with a portion of the genito-urinary organs and their appendages, and of which the circumference corresponds in a great measure to the periphery of the inferior aperture of the pelvis; in the present article, however, it is intended to describe the perineum in the male subject only, as the parts which it comprises in the female are noticed in detail under other headings in this work.

The limits which we would assign to this region are sufficiently precise: superiorly, or towards the abdominal cavity, it extends as far as the reflections of the recto-vesical layer of the pelvic fascia and the great cul-de-sac of the peritoneum, including within its precincts the prostate gland and the neck of the bladder, together with a part of the inferior surface of that viscus and the vesiculæ seminales and vasa deferentia; inferiorly, the perineum is quite superficial, being covered by the integuments only; and it is circumscribed partly by the fixed boundaries of the inferior aperture of the pelvis, and partly by the obturator fascia, an aponeurotic expansion which appears to line a portion of the inner surface of the os innominatum, but is in reality separated from the bone by the obturator internus muscle and the internal pudic vessels and nerve.

In describing this complicated region it will be advantageous to consider in the first place the osseous and ligamentous structures which circumscribe the inferior outlet of the pelvis, and to notice in a general manner the course of the rectum and urethra, together with so much of the urinary bladder as is connected with the perineum, for in the sequel it will appear that the rectum and the urethra are the principal elements of the region, and that almost all the other parts contained in it are appendages of either the one or the other, so that by the adoption of this method a key to the anatomy of all the subordinate structures will be obtained.

The inferior aperture of the male pelvis examined after the removal of the soft parts (the sacro-sciatic ligaments being preserved) is diamond-shaped; it is limited anteriorly by the arch of the pubis, posteriorly by the extremity of the coccyx, and laterally by the rami of the pubis and ischium, the tuberosity of the ischium, and the great sacro-sciatic ligament at each side respectively. It presents three diameters, viz. the antero-posterior, the transverse, and the oblique. The first extends from the coccyx posteriorly to the symphysis pubis in front; the second passes transversely between the tuberosities of the ischia; and the third stretches from the point midway between the tuber ischii and the arch of the pubis, to the centre of the great sacro-sciatic ligament of the opposite side. In a well-formed male pelvis these three diameters are almost equal, being each of them nearly three and a-half inches in extent; but in consequence of the mobility of the coccyx that bone may be moved backwards considerably, and under such circumstances the antero-posterior diameter becomes increased to a corresponding amount.

This large space admits of a very natural division into two triangles, one in front, the other posteriorly; the base of each respectively corresponds to the line passing transversely between the tuberosities of the ischia, and the apex of the one is formed by the arch of the pubis, whilst that of the other is constituted by the extremity of the coccyx.

The anterior triangle is equilateral; its sides are formed by the rami of the ischium and pubis, and are each from three inches to three and a-half inches in length; it contains the urethra and the root of the penis, with their appendages, and may be named the urethral division of the perineum.

The posterior triangle is bounded laterally by the great sacro-sciatic ligaments, and in the recent state by the edge of the gluteus maximus muscle also. The coccyx usually protrudes forwards so much that the area of the posterior triangle is less than that of the anterior, notwithstanding that the base of each of them is represented by the same line. This posterior triangle contains the anus with the inferior portion of the rectum, &c., and is usually called the anal division of the perineum.

It should be borne in mind that the measurements of the inferior outlet of the pelvis may present considerable variations in different subjects, and that the operator may be obliged to modify the length and the direction of his incisions in lithotomy to suit such cases. M. Dupuytren, for example, in twenty-three subjects which he examined, found the distance intermediate between the tuberosities of the ischia to vary from two inches to three and a-half inches; and M. Velpeau, who measured forty subjects, observed in one case these processes to be but an inch and three quarters asunder, whilst in another they were four inches apart.

In order to perform successfully many of the operations in this region the surgeon requires an accurate knowledge of the axes of the pelvis, and to study the modifications which these imaginary lines exhibit in childhood and old age as compared with adult life. In the full-grown male the axis of the superior aperture of the true pelvis takes a direction from the vicinity of the umbilicus downwards and backwards to the coccyx, whilst the axis of the inferior aperture passes upwards and slightly backwards through the mid space between the tuberosities of the ischia to the promontory of the sacrum; these two lines intersect each other in the pelvic cavity, forming an angle slightly obtuse and salient posteriorly: the axis of the true pelvis (or in other words a line passing through the centres of the upper and lower apertures respectively) is therefore a curved line concentric with the curvature of the sacrum, and having its concavity directed forwards and downwards towards the symphysis pubis.

During childhood the true pelvis is imperfectly developed; it has but little depth, and its capacity is so limited that the viscera which occupy the pelvis of the adult are mostly contained in the abdominal cavity of the infant. The straits of the pelvis have each of them likewise an aspect different from that of the adult; in the child the superior aperture looks much more directly forwards, and the inferior aperture much more backwards than they do after puberty. These peculiarities are inherent in the infantile pelvis: they are independent of any inclination in the vertebral column, and they must therefore modify considerably the direction of the pelvic axes during the early years of growth.

In the old subject again the superior aperture is once more directed forwards as in the infant, whilst the inferior aperture inclines backwards; at this period of life, however, the change in the pelvis arises not from any intrinsic alteration in its bony parietes, but simply from the senile curvature of the spine above, added to the habitual flexion of the hip and knee-joints below, so constantly observed in the aged individual.

To understand the course of the rectum and the urethra, as well as the relations of the base of the bladder, the anatomist must study these parts within the pelvis, since it is impossible to display them satisfactorily in the ordinary dissection of the perineum; much assistance may be derived from preparations affording a side view of the pelvic viscera, and one of the most useful is an antero-posterior section carried through the middle line and dividing the urethra, prostate gland, bladder, and rectum, &c., after these organs have been moderately distended and hardened by alcohol.

Rectum.—The portion of intestine which belongs to this region commences at the great cul-de-sac of the peritoneum and terminates at the anus. It is perfectly devoid of any serous investment, and presents considerable varieties in size and direction in different subjects. The age and the habits of the individual are found to exert a remarkable influence upon its course and dimensions, and accidental variations in the line of reflection of the serous membrane, which create corresponding changes in the depth of the perineum, are occasionally observed even in the adult, and ought to be taken into account by the operator.

The great cul de-sac of the peritoneum is usually about three-and-a-half inches distant from the anus, so that, making allowance for the curved course of the intestine, we may estimate the length of the perineal portion of the rectum in the adult at somewhat less than four inches. In forming this estimate, the condition of the urinary bladder as regards its distension should not be overlooked, for when that reservoir is empty and contracted, the rectum receives an extensive serous investment, and at such times the cul-de-sac of the peritoneum approaches the anus perceptibly, whilst under the opposite condition (that of repletion) the bladder displaces the serous membrane partially, carrying its cul-de-sac upwards towards the abdomen. Individual varieties, irrespective of these changes in the bladder, are, however, of constant occurrence, and in many instances the rectum in the adult is covered by serous membrane anteriorly to within two inches of the anus, the bladder being at the same time fully distended. In the young subject the peritoneum stretches very far downwards along the surface of the bowel, and at birth it very generally covers the front of the rectum to within one inch of the anus; at the age of five years the cul-de-sac of the peritoneum and the anus are still separated by a very trifling interval; but from this period up to puberty the intermediate distance gradually increases, *pari passu*, with the growth of the pelvis and the developement of the inferior fundus of the bladder.

At its commencement the perineal portion of the rectum runs obliquely downwards and forwards, this direction it maintains as far as the prostate gland, but it there alters its course and turns slightly backwards to terminate at the anus. Superiorly it presents a slight curvature concentric with that of the sacrum, so that the anterior surface of the gut is there slightly concave, and its posterior surface slightly convex from above downwards: inferiorly, however, the curvature of the intestine is reversed; it appears as it were to turn round the point of the coccyx to gain the anus, and therefore the convexity of the lower part of the gut is directed forwards whilst its concavity looks backwards. This curved course of the rectum ought to be borne in mind by the surgeon in his attempts to introduce instruments into its interior.

In the child the sacrum and coccyx present but a trifling curvature, and therefore the rectum reaches the anus by a less circuitous route than that just described, and which is the normal condition in the adult; during childhood the inclination backwards of the lower extremity of the gut scarcely exists, it possesses but a single curve concave forwards, which, like that of the sacrum and coccyx, is but faintly marked, so that the intestine is much straighter in early life than after puberty. In old age the rectum immediately above the anus is sometimes inflected from side to side so as to assume a zigzag appearance: these lateral inclinations are the result of the enormous enlargement which the bowel occasionally undergoes in the advanced periods of life, its length being actually increased at the same time that its cavity is dilated.

In the adult subject the rectum is somewhat cylindrical in shape, but it increases in capacity as it descends, and presents a marked dilatation just above the sphincters, whilst the anus and so much of the gut as is embraced by those muscles exhibit a decided contraction. In the child the dilatation just described is but little marked, whilst in advanced life it very frequently becomes excessive, and is best appreciated when the intestine is fully distended with fæces or artificially inflated; under such circumstances the anterior wall of the rectum is hollowed into a deep depression or gutter, in which the prostate gland and base of the bladder are imbedded, and the bowel swells outwards and forwards upon each side of the prostate, losing altogether its cylindrical shape. It will be readily understood that when such a disposition prevails in a calculous subject, the rectum must undergo serious danger during lithotomy performed according to the lateral or bilateral methods, and that therefore the precaution of emptying the bowel previous to these operations is highly advisable.

The relations of the perineal portion of the rectum deserve from the surgical anatomist his most attentive consideration. Anteriorly the inferior fundus of the bladder, together with the vesiculæ seminales and vasa deferentia, come into contact with the rectum immediately beneath the line of reflection of the peritoneum; lower down the prostate gland rests upon the front of the rectum, to which it is very intimately connected, nothing but some cellular tissue intervening between them, whilst still lower down the membranous portion of the urethra and the bulb are related to the rectum, though not immediately, for neither of those parts of the urinary apparatus is found to *touch* the parietes of the gut. The bulb of the urethra in the adult is usually situated about half an inch in front of the rectum and about one inch above the anus; the membranous portion of the urethra lies about ten lines anterior to the rectum, and rather more than an inch and a half above the anus, whilst the prostate gland is placed within one line of the anterior wall of the gut, and about two inches above the anus. These anterior relations of the rectum explain how the finger introduced into its cavity may assist the catheter in its passage along the urethra in the living subject; how by the same manœuvre the surgeon obtains valuable information as to the state of the bladder and prostate gland in various morbid conditions of those organs; how, in sounding, he is able at times to raise up the calculus by his finger so as to bring it into contact with the instrument; how the bladder may be punctured from the rectum and the urine withdrawn by this route in certain cases of retention; how, acute inflammations and other diseases of the bladder and urethra or their appendages so frequently occasion morbid sympathies in the intestine, such as prolapsus, tenesmus, hemorrhoids, &c.; and above all, how great must be the danger to the bowel, and how urgent the necessity for protecting it during the lateral operation of lithotomy.

Posteriorly a quantity of loose cellular tissue connects the lower part of the rectum to the sacrum and coccyx; it is there related, particularly when distended, to the pyriformis and ischio-coccygeus muscles, and towards its anal extremity to some of the fibres of the levatores ani and the ano-coccygeal ligament.

On either side the rectum gives insertion to a portion of the recto-vesical layer of the pelvic fascia, which, though weak and cellular in that locality, nevertheless admits of being fairly traced to the walls of the gut; but the levatores ani muscles constitute the principal lateral relations of the intestine. In their descent they cover its surface extensively, and form in great measure the partition between the bowel and the ischio-rectal fossæ.

The perineal portion of the rectum affords in some respects a striking contrast to the upper part of the same intestine; being totally devoid of serous investment, it is more fixed and (except at the anus) more dilatable than the superior division of the bowel, and its connexions with the recto-vesical layer of the pelvic fascia, the ano-coccygeal ligament, the genito-urinary passages, and the middle tendinous point of the perineum, contribute to fix it still more firmly in its position.

The coats of the rectum present certain peculiarities interesting to the surgical anatomist. Its muscular tunic is of uncommon strength, and consists of two very distinct layers analogous in many particulars to those of the corresponding strata in the œsophagus; the superficial layer is formed of highly developed longitudinal fibres, florid in colour (as contrasted with those of the remainder of the large intestine), and which spread out so as to invest the whole circumference of the gut: the fibres of the deeper layer are circular, and acquire increased developement towards the anal extremity of the intestine, where they are continuous with the internal sphincter. The mucous membrane is remarkable for its thickness and vascularity and for the great laxity of its connexion with the other tissues of the gut: it adheres so loosely to the subjacent coat in the vicinity of the anus that it sometimes protrudes through that opening, and in this manner one form of prolapsus ani is produced.

Upon the free surface of the mucous membrane a number of longitudinal folds run down to the immediate neighbourhood of the anus; they are called the columns of the rectum, and converge slightly as they descend; their number is variable though it seldom exceeds eight or ten, and between them inferiorly some transverse semilunar folds may be observed, of which the free concave margins are directed upwards. In these folds of the mucous membrane the physiologist recognises a provision to facilitate the distension of the gut, and to their presence some surgeons attribute the occurrence of certain morbid conditions of the intestine. In addition to these folds, which are constant, others have likewise been described within the rectum; these latter were named by the late Dr. Houston "the valves of the rectum," and appear at times remarkably distinct. When present they are each of a semilunar shape, and formed by a duplicature of mucous membrane containing cellular tissue and a few muscular fibres between its folds. Each valve is attached by its convex margin to the walls of the gut, whilst its free edge is directed more or less inwards towards the cavity of the intestine. One of these valves is situated (according to Houston's statement) opposite to the base of the bladder, on the anterior wall of the gut and about three inches distant from the anus, whilst another is sometimes placed within one inch of the anal orifice.

That projections from the parietes of the rectum, such as have been described by Houston, may be made apparent by a certain mode of preparation cannot be denied, but that they can or do exert much influence in supporting the weight of the column of fæces within the intestine, or in obstructing the progress of instruments through it, may be very fairly questioned; for when the rectum has been removed from the dead subject and laid open, these valves are in general no longer visible, and the natural curvatures of the bowel explain sufficiently the difficulties encountered in the introduction of rectal tubes or bougies in the living.

Bladder, vesiculæ seminales, and vasa deferentia.—It is here necessary to notice briefly so much of the under surface of the bladder as is uncovered by peritoneum, and to consider in a cursory manner the vesiculæ seminales and vasa deferentia. These structures are situated very deeply in the perineum, and therefore they are dissected with advantage from within the pelvis.

On looking down into the pelvic cavity in a recent subject after the peritoneum has been displaced and the bladder drawn gently to either side, the anatomist obtains a satisfactory view of the course and connections of the recto-vesical layer of the pelvic fascia, which there constitutes the superior boundary of the perineum. The recto-vesical is the innermost layer of the pelvic fascia; after investing the inner surface of the levator ani muscle it is reflected upon the prostate gland and side of the bladder, and more posteriorly upon the rectum; a line drawn from the lower extremity of the symphysis pubis to the spinous process of the ischium is nearly the level at which this reflection takes place. This fascia is closely connected in front to the upper surface of the prostate gland, and in that situation it forms the anterior true ligaments of the bladder; it next adheres to the edges of the gland, and more posteriorly to the sides of the bladder, there constituting the lateral true ligaments of that viscus; whilst still further back it is identified with the sides of the rectum as has been already described. Its attachments to the bladder at either side respectively are situated a little above the vesiculæ seminales.

This fascia forms the line of demarcation between the perineum and the upper portion of the pelvic and the abdominal cavity. It is of sufficient strength to resist powerfully the descent of any of the abdominal viscera through the space between the bladder and the parietes of the pelvis, and affords equal resistance to the progress upwards of matter or other effusions from below; it may be considered as a sort of shelving roof to the perineum, and a concave floor to the abdomen. Its density and strength are at their maximum in front, whilst both these properties diminish as it approaches the rectum. Above it, is found a quantity of loose adipose cellular membrane, continuous without line of demarcation with the subserous tissue of the abdomen, whilst below it are situated the cellular tissue of the perineum and the several parts comprised in the depths of that region. His knowledge of its connections teaches the anatomist that urine effused above the level of this fascia must soon reach the peritoneum and produce the most disastrous consequences; whilst the experienced surgeon endeavours in every operation upon the perineum to limit his incisions, so as to spare the fascia now under consideration.

That portion of the inferior surface of the bladder which projects into the perineum is bounded posteriorly by the peritoneal cul-de-sac, and extends forwards as far as the prostate gland, whilst the line along which the recto-vesical fascia takes attachment to the bladder forms its lateral limits. The dimensions of this part of the bladder are exceedingly variable, being modified by the degree of vacuity or repletion of the organ itself at the time of examination, as well as by the age of the individual; but its measurements are always much greater transversely than from before backwards. In the adult it is in general of moderate extent, but it increases considerably when the urinary reservoir is fully distended, and it diminishes as that viscus becomes empty, whilst the variable depth of the cul-de-sac of the peritoneum (already dwelt upon in a former part of this article) is calculated still further to render its size uncertain. In the child this region of the bladder scarcely exists, an anomaly explained by the pyriform shape of the organ in early life, the narrow neck of the bladder being then its most dependent portion, and the peritoneum being prolonged very far downwards towards the anus. In old age the perineal portion of the bladder often exhibits extraordinary developement, becoming by far the lowest part of the whole organ, and forming a pouch which projects remarkably towards the rectum. In many instances calculi become lodged within this depressed part of the viscus, far beneath the level of the cervix vesicæ, so as to elude detection by the sound; and in this manner is explained the valuable assistance which the finger introduced into the rectum so frequently affords the surgeon in exploring the bladder for a stone. The perineal portion of the bladder rests in great measure upon the rectum; in the middle line it is in immediate contact with the gut, but towards either side a part of the vesicula seminalis and vas deferens is interposed.

This region of the bladder has received special attention from anatomists in consequence of its presenting a small triangular space, in which the operation of recto-vesical paracentesis is, or ought to be, performed. The triangular space in question is usually small and very nearly equilateral; its base, directed backwards and upwards, is formed by the peritoneal cul-de-sac; the vasa deferentia and the vesiculæ seminales to the right and left respectively constitute its sides, whilst the notch in the prostate gland represents its apex. The surgeon ought to consider carefully the extent of surface which the area of this triangle comprises, as well as the average distance from the anus at which it is placed; for should the bladder be punctured behind this "place of election," the peritoneum must be wounded; and should the trocar be introduced in front of it, the prostate gland and common ejaculatory ducts would be endangered, whilst the slightest deviation to either side brings the corresponding vas deferens and vesicula seminalis into peril. In the majority of full-grown subjects the space under consideration is about three inches distant from the anus, so as to permit the index finger of the operator to reach it without difficulty; but from statements already made the reader will perceive that many exceptions to this rule may be encountered in practice. Again, the sides and base of this triangle (so long as the neighbouring parts remain in situ) are in general each of them respectively less than one inch in length; yet when the bladder is removed from the subject and artificially distended, and when the connections of the peritoneum are disturbed by dissection, the space to which we refer becomes immensely enlarged, and the anatomist is then apt to form a most exaggerated and erroneous idea of its *natural* dimensions.

Against the recto-vesical paracentesis many very serious objections may be raised. In early life it should not be attempted, because at that period the peritoneum descends so low, and the under surface of the bladder is so little developed, that injury to the serous membrane of the abdomen would almost necessarily ensue. Even in the adult the great uncertainty of the depth of the peritoneal cul-de-sac, added to the utter impossibility of ascertaining its extent in the living subject, constitutes a weighty argument against the operation; whilst the enlarged prostate (so very common in old men) must frequently forbid its performance in after life; and the danger of wounding the vas deferens or the vesicula seminalis, or of producing urinary infiltration or a permanent fistula, may be fairly urged against this mode of relieving the bladder, at whatever age undertaken. The other methods employed for the same purpose in extreme cases of retention of urine are also no doubt open to valid objections, but any further consideration of this subject would be out of place in the present article.

In order to perform lithotomy successfully, or to tap the bladder with safety, the surgeon should ever bear in mind the direction of the axis of that organ. In the adult male the axis of the bladder runs nearly parallel to the axis of the upper strait of the pelvis; but upon a lower plane, that is to say, nearer to the pubis, if produced, it would pass superiorly through the linea alba between the umbilicus and the pubis, and it would touch the inferior extremity of the coccyx below. In the child its direction is very variable, for the urinary reservoir being then in the abdomen and in contact with the anterior wall of that cavity, must necessarily move in obedience to the abdominal muscles, and every change of position which the bladder undergoes exerts a marked influence upon its axis. During childhood the axis of the bladder appears in *the dead subject* to run from before backwards nearly horizontally, because the distended bladder, no longer supported by the abdominal muscles, turns forwards over the pubis; but in *the living child*, when the recti abdominis are forcibly contracted, the line in question becomes nearly vertical.

The urethra.—Anatomists describe the urethra as a canal presenting a double curvature, of which the anterior segment is highly moveable, and of which the posterior is in a great measure fixed. The anterior segment (comprising the spongy portion of the urethra from the meatus urinarius to the vicinity of the bulb) exhibits, in the flaccid condition of the penis, a marked curvature concave downwards, which disappears, however, during erection, and which exerts little influence upon catheterism, since the surgeon easily obliterates it by raising the penis until it forms an angle of about forty degrees with the anterior wall of the abdomen. The posterior segment (consisting of the whole of the prostatic and membranous portions of the urethra, and also of the posterior part of its spongy portion) presents on the contrary a permanent curvature concave upwards, and belonging essentially to the perineum, it requires in this place a special description. To dissect the perineal portion of the urethra with advantage, the anatomist ought to remove the greater part of the ossa pubis and the ascending rami of the ischia from a recent subject, with the penis, the bladder, and the rectum attached; this can be easily accomplished by cutting the horizontal ramus of the pubis at each side perpendicularly with a saw as near the acetabulum as possible, after which the instrument may be made to traverse the foramen ovale, and divide the ramus of the ischium in the immediate vicinity of its tuberosity. If the bladder be then inflated from one of the ureters, and the rectum distended, the preparation will exhibit in a satisfactory manner the urethra and many other parts described in this article, of which but an imperfect view is obtained in the ordinary dissection of the perineum from below.

The posterior segment of the urethra represents a reversed arch, of which the centre lies about ten lines beneath the symphysis pubis, whilst the extremities incline upwards, the one in front and the other behind the symphysis. Ample provisions exist to render this arch permanent; its centre, constituted by the membranous portion of the urethra, is transmitted through the triangular ligament, and adheres by its circumference to the edges of the opening through which it passes; its posterior extremity, formed by the prostatic urethra, is tied up to the back of the pubis by the anterior true ligaments of the bladder, whilst the true suspensory ligament of the penis in front, and the prolonged attachments of the crura penis, pinning that organ up to the anterior surface of the pubis, raise the spongy portion of the urethra at its commencement, and consequently elevate the anterior extremity of the arch. The permanency of this arch depends of course mainly upon the strength and resistance of the aforesaid ligaments; yet, although the properties of these structures are well known to anatomists, a difference of opinion prevails as to the possibility of rendering the urethra straight by simple traction of the penis.

The true suspensory ligament is calculated by its position and strength to prevent the surgeon from depressing the penis sufficiently to straighten the urethra, and in the dead subject no force so applied, short of what suffices to tear the ligament in question and to rupture partially the attachment of the crura penis to the bones, can efface the curvature of the posterior segment of the canal, but if the suspensory ligament be divided by the knife, and if at the same time the crura penis be detached ever so little from the pubis, the slightest traction exercised subsequently upon the penis renders the urethra perfectly straight. The writer by no means intends to deny that catheterism by straight instruments is a feasible operation: to straighten the urethra by drawing the penis in certain directions, and without any other aid, is one thing, and to introduce a straight instrument into the bladder along the urethra is a totally different matter; to accomplish the former, either in the living or the dead subject, so long as the true suspensory ligament is uninjured and the crura penis retain their attachments, will be found absolutely impossible, whilst the latter operation may very generally be performed by any surgeon who possesses ordinary dexterity. The principle on which the introduction of straight instruments is effected admits of ready explanation. By raising the penis as before described the operator renders the urethra, from the glans to the bulb inclusive, perfectly straight, and therefore the staff traverses the passage so far without impediment, but any attempt to force it farther in the same direction would rupture the lower wall of the urethra, and propel the point of the instrument towards the rectum. The hinder portion of the canal leads upwards and backwards to the bladder, and it therefore remains to be explained how a straight instrument, occupying the spongy part of the urethra, and with its point directed downwards and backwards towards the rectum, can have its course so changed as to pass upwards and backwards to the bladder. The solution of the problem is easy: the handle of the instrument is first drawn forwards so as to form a right angle with the pubis, and then depressed until it becomes nearly parallel with the patient's thighs, whilst at the same time an onward movement is communicated to it, whereby the point glides upwards and backwards into the bladder. In these movements the staff obviously represents a lever of the first order, the fulcrum formed by the lower wall of the urethra opposite to the true suspensory ligament of the penis, and the beak of the instrument being elevated as its handle is depressed.

In addition to its curvature, that part of the urethra which belongs to the perineum presents other features of interest to the surgical anatomist. In the dead subject its diameter is naturally far from uniform, whilst in the living its calibre is exceedingly liable to vary, according to the contraction or relaxation of the muscular expansions which in certain situations invest it. Its parietes also exhibit in many places peculiarities of organisation calculated to embarrass the surgeon, and therefore some further notice of this part of the canal becomes here necessary.

The prostatic portion of the urethra is an inch and a quarter or at most an inch and a half in length. In the adult it takes an oblique direction from above and behind downwards and forwards; but in the aged subject it runs more horizontally, a change produced by the developement of the "bas fond" of the bladder; and in the child its course is nearly vertical in consequence of the position of the bladder at that period of life. The prostatic urethra is slightly contracted at each extremity, whilst in the intermediate space it is somewhat widened, the dilatation being most observable near its lower wall. The verumontanum or caput gallinaginis, a prominent fold of mucous membrane, extends in the middle line along the floor of this part of the canal: it exhibits anteriorly a depression named the sinus pocularis, the orifice of which is directed forwards, whilst on either side the aperture of the common ejaculatory duct usually opens. The verumontanum is placed between two deep depressions called the prostatic sinuses; these contain numerous orifices of the prostatic ducts, a few only being observable on the upper wall of the urethra. At the posterior extremity of each sinus a transverse fold of mucous membrane, of which the free concave margin looks forwards, may be occasionally observed; this has been called the "pyloric valve" by M. Amussat; but in the majority of subjects no such structure exists, and when present it is generally occasioned by an incipient enlargement of the third lobe of the prostate gland, which, projecting upwards from below, elevates the mucous membrane at either side, so as to produce the valvular arrangement in question.

From this brief exposition it follows that many impediments to catheterism may be encountered in the prostatic portion of the urethra. The ducts which open upon its walls having their orifices mostly directed forwards, are sometimes morbidly enlarged, when they might easily arrest the point of a fine bougie; whilst the prostatic sinuses forming depressions below the level of the floor of the urethra and the folds of mucous membrane just described, are also calculated at times to entangle a small-sized instrument. Most of these impediments are situated along the floor of the urethra, and from their very nature they are likely to obstruct none but the smallest instruments. To avoid them, therefore, the surgeon should if possible select an instrument of large size and direct the point along the upper wall of the passage. The difficulties of catheterism are sometimes vastly increased by disease of the prostate gland, but obstructions of that description are beyond the scope of this article. The remarkable sympathy so constantly observed in practice between the testicle and the urethra is explained by the manner in which the lining membrane of the vas deferens becomes continuous with that which carpets the urethra at the orifice of the common ejaculatory duct.

The membranous portion of the urethra is intermediate between the prostatic and the spongy portions of that canal. *In situ* its length seldom exceeds three quarters of an inch, but when detached and extended it appears about an inch long. Its direction is nearly horizontal, but its upper surface presents a very slight curve, concave towards the pubis. Its under surface is overlapped from before by the bulb, a disposition which diminishes somewhat the apparent length of its lower wall. Its anterior extremity is fixed by the triangular ligament of the urethra, a structure of uncommon strength, through which it passes; but posteriorly it projects behind the triangular ligament for a short distance, and being there girded by Wilson's muscles, which support it like a sling, it possesses in that situation considerable mobility. The membranous portion of the urethra is naturally the narrowest part of the canal, presenting in this respect a marked contrast to the prostatic and spongy portions. Its parietes are endowed with considerable powers of resistance, being strengthened in front by the triangular ligament, which sends forwards upon them an expansion continuous with the fibrous covering of the bulb; whilst a still stronger expansion derived from the back of the triangular ligament surrounds the urethra beneath Wilson's muscles, and affords it powerful protection posteriorly. Between this latter investment and the mucous membrane a peculiar structure exists of which the exact nature is rather doubtful, some considering it a modified erectile tissue, whilst others look upon it as muscular.

The membranous portion of the urethra merits from the surgical anatomist an attentive consideration. It is here that the operator lays bare the groove of the staff in lithotomy performed after the lateral or bilateral methods; this is the situation in which spasm usually arrests the catheter, the obstruction being produced by undue action of Wilson's muscles. Foreign bodies, such as calculi, are very likely in consequence of its diminished calibre to be impacted in this part of the canal, and its anterior extremity is frequently the site of permanent stricture.

In using a curved catheter the surgeon should slacken the penis upon the instrument so soon as its point has fairly traversed the triangular ligament; for if, during the further depression of the handle, the penis be forcibly stretched upon the catheter, its point may push the upper wall of the urethra against the back of the pubis, and in that manner produce considerable mischief. It is also of advantage to communicate a slightly onward movement to the catheter at this part of the passage, as the bladder is situated much more posteriorly, and in the introduction of any instrument, whether curved or straight, it should be borne in mind that spasmodic obstructions yield in general to gentle but continued pressure, and that attempts to force such strictures are usually productive of increased spasm, and, if persisted in, of laceration of the urethral canal.

In connexion with the perineum, so much of the spongy portion of the urethra only as is covered by the acceleratores urinæ muscles requires to be considered, and of this the bulb constitutes the largest and most important part. The bulb is an oval swelling, in which the corpus spongiosum urethræ commences posteriorly, it varies in size according to the subject, being small during childhood, enlarging very much at puberty, and often presenting excessive dimensions in old men; during erection, too, it is turgid and swollen, though at other times it remains comparatively flaccid. The length of the bulb, when well developed, may be estimated at an inch and a half, and its thickness or depth from the cavity of the urethra at about eight lines. Its posterior extremity is thick and overlaps the membranous portion of the urethra, whilst anteriorly the bulb becomes gradually narrower, but there is no exact line of demarcation between that body and the remainder of the corpus spongiosum. The bulb is situated between the crura penis and in front of the triangular ligament of the urethra, to which it is connected by the expansion of fibrous membrane already described; it is covered by the acceleratores urinæ, and derives from them a muscular sheath all but perfect. The bulk of this body is constituted by a spongy erectile tissue, remarkably soft, and possessing intrinsically little powers of resistance, but a thin fibrous membrane of investment affords it some protection from without. The canal of the urethra in this situation presents a slight dilatation (most observable inferiorly) named the sinus of the bulb, and the delicate ducts of Cowper's glands, two in number, open into the lower and lateral parts of the passage still further forwards. It should be particularly noted that the bulb, *measured at the exterior*, is in point of size quite out of proportion to the width of the corresponding part of the urethral canal, the canal presenting but a slight dilatation, whilst the dimensions of the bulb are very considerable; and of equal importance in practice is the fact that the axis of the bulb differs widely from the axis of the corresponding portion of the canal, the axis of the bulb running in a very oblique direction downwards and backwards towards the lower extremity of the rectum, whilst the axis of the canal lies upon a higher plane and runs much more nearly horizontally backwards.

In a healthy urethra the principal difficulties of catheterism, whether performed by straight or by curved instruments, are encountered at this part of the passage: the sudden change in direction which the urethra here undergoes, the abrupt narrowing of the membranous portion immediately behind the dilatation of the bulb, the mobility of the urethra in front of the triangular ligament, and its immobility where it passes through that structure, the ease with which a catheter perforates the delicate tissue of the bulb, and, above all, the striking difference in direction observable between the axis of the bulb and the axis of the corresponding portion of the urethral canal, explain this sufficiently; nor should it be forgotten that the muscular girth formed by the acceleratores urinæ is often the seat of spasm.

The error in catheterism of most frequent occurrence here is the perforation of the floor of the urethra at the bulb, after which the extremity of the instrument passes between the rectum and the urethra. The surgeon commits this mistake by neglecting to depress the handle of the catheter in time to raise the point out of the sinus of the bulb into the membranous portion, and so much the more readily as the slightest force exercised in this wrong direction is sufficient to perforate the spongy tissue.

The premature depression of the handle of the catheter may likewise injure the urethra, but in a different manner, for if that manœuvre be executed too soon and with undue force, the point of the instrument will lacerate the *upper* wall of the canal anterior to the triangular ligament.

A difficulty may, however, be experienced in entering the membranous portion of the urethra, even though the handle of the catheter be depressed at the proper time; the surgeon in such cases fails to "hit off" the aperture in the triangular ligament which transmits the urethra, and the point of the instrument swerving laterally, comes to press against the front of the triangular ligament at one side of the orifice, instead of traversing the orifice itself. To guard against such a casualty, care must be taken to keep the point of the catheter fairly in the middle line, and (should any obstruction arise) to exercise slight traction upon the penis for the purpose of rendering tense the fibrous covering of the bulb, and in that manner stretching the opening in the triangular ligament.

From these principles it clearly follows that, except under peculiar circumstances, curved instruments are to be preferred, for their adaptation to the curvature of the canal enables them to reach the bladder without exercising undue pressure upon any part of the passage; whilst the straight staff conducted ever so skilfully must to a certain extent strain or disturb the permanently curved portion of the urethra. But, besides this obvious advantage, the natural impediments to catheterism (placed chiefly along the floor of the passage) are also most easily surmounted by the curved instrument, for its point can at any moment be readily raised by the operator, whilst he accomplishes the same object much more imperfectly in using the straight staff. It cannot be denied, however, that, for certain purposes, straight instruments possess a decided superiority, and therefore every surgeon should be prepared to employ them when the occasion suits.

The preceding outline describes with sufficient accuracy the course and relations of the principal organs belonging to the perineum, and therefore it now only remains to study the anatomy of this region from below, according to the usual method of dissection. The subject is of course supposed to be placed in the ordinary position, with a full-sized staff introduced into the bladder, the rectum artificially distended, the scrotum raised and drawn forwards, the hands bound firmly to the ankles at each side respectively, the pelvis elevated on a block, and the knees separated to a convenient distance from each other.

Prepared in this manner, the perineum presents anteriorly a well-marked median prominence corresponding to the urethra, and which for obvious reasons enlarges considerably in the living subject during erection. At either side of this urethral prominence a parallel depression exists, external to which the resisting edges of the rami of the ischium and pubis may be always readily recognised by the finger. At the posterior part of the perineum the point of the coccyx may be felt distinctly in the middle line; the tuberosities of the ischia covered by a great depth of soft parts project remarkably at the sides, constituting the extreme lateral limits of the region, whilst the mid space between these eminences exhibits a deep depression containing the anus. In front of the anus a central elevation of the skin termed the raphé extends forwards along the perineum, and may be traced distinctly to the scrotum and penis; it serves as a guide to the surgeon in many operations, pointing out the middle line accurately so long as the integuments retain their normal relations.

Integument.—The characters of the cutaneous covering of the perineum are not uniform throughout; in some situations its thickness is very considerable, whilst in others it appears remarkably delicate. In front the skin becomes gradually finer as it approaches the scrotum, and at the margins of the anus its delicacy is extreme; but in the neighbourhood of the tuber ischii and along the edge of the gluteus maximus it possesses great density and offers considerable resistance to the scalpel: at the circumference of the region it in fact gradually assumes the properties of the neighbouring tegumentary membrane, resembling that of the scrotum anteriorly, merging insensibly into the integument of the buttock and thigh laterally, and even approaching to the characters of mucous membrane in the vicinity of the gut; it is generally of a dark brown colour in the healthy adult, and of a lighter hue in the child; but there are in this respect numerous individual varieties; the darker the teint the more highly developed usually are the subjacent muscles. Cutaneous follicles abound in the perineum and occur in greatest numbers near the anus and at the root of the scrotum, where their secretions are most required. The skin around the anus is thrown into rugæ disposed in a radiated manner, and which produce a puckered appearance so long as the orifice remains contracted: they disappear during its dilatation, and are designed to favour the extreme distension to which the anal extremity of the intestine is occasionally subjected during defæcation. The folds in question become at times the seat of fissure, ulceration, or excrescence, which may demand surgical interference for their relief.

In the lateral operation of lithotomy the first incision should commence at the left side of the raphé, about an inch or an inch and a quarter in front of the anus, and extend in an oblique direction backwards and outwards to the point midway between the tuber ischii and the orifice of the gut. In the bilateral operation the first incision is semilunar, the cornua placed at either side between the tuber ischii and the anus, and equidistant from these points respectively, the centre situated about three quarters of an inch in front of the anal aperture, and the concavity of the curve directed backwards. For convenience the operator in general begins this incision on the right side of the perineum.

On removing the integuments the anatomist brings into view anteriorly the superficial fascia of the perineum, surrounding the anus the cutaneous sphincter, and at either side of the gut a large quantity of adipose cellular tissue, which fills up in great measure the interval between the intestine and the tuber ischii. If the dissection have been carefully conducted, some nervous twigs are also visible near the rami of the ischium and pubis; they are mostly cutaneous and derived from the sciatic branch of the lesser sciatic nerve (the "perineal cutaneous" of many authors, the "long inferior pudendal" of Sœmmering) in its course to the scrotum and root of the penis. This nerve or its branches are always superficial and liable to injury in many operations performed upon the perineum.

The superficial fascia.—The superficial perineal fascia has been by some anatomists described as two membranes essentially separate and distinct from each other, that nearer to the surface being called the "subcutaneous cellular membrane" of the region, and the deeper of the two being designated "the superficial fascia of the perineum." To the writer this description appears unnecessarily minute, for in fat subjects it is exceedingly difficult to effect such a separation, and under the most favourable circumstances the dissection in question is too artificial; with equal propriety might the superficial fascia of the abdomen be divided into layers, for like that in the perineum, its cutaneous surface is cellular and often loaded with fat, whilst its deeper surface assumes very much an aponeurotic appearance.

The superficial perineal fascia is a celluloaponeurotic expansion interposed between the integuments and the principal muscles, &c. of the region, (to this, however, the superficial sphincter muscle, which is absolutely subcutaneous, forms an exception;) in the anterior or genito-urinary division of the perineum it is of very considerable thickness, being mostly cellular and fatty superficially, and becoming more dense the deeper the dissection is carried; numerous fibrous bands are interwoven with this expansion, and appear more and more evident the farther from the integument it is examined, so that at length, just like the superficial fascia of the abdomen, it assumes very much the characters of fibrous membrane. The varieties in density which this fascia presents in different subjects are nearly endless; in corpulent persons its grossness is sometimes excessive, and when condensed by inflammation its depth becomes extreme: this explains the surprising distance from the surface to which the surgeon usually cuts in liberating the matter of a perineal abscess, and shews the lithotomist the necessity of duly estimating the thickness of this structure before he commences his operation. Traced forwards the superficial fascia becomes gradually thinner until at length it degenerates into cellular membrane continuous almost without line of demarcation with the dartos, and as it approaches the scrotum it becomes loose in texture, whilst its cells communicate freely with each other and contain little adipose substance, if any. Followed laterally it seems at first sight to merge gradually into the subcutaneous cellular tissue of the thigh, but when examined from beneath by being raised in a flap from the middle line outwards, it is found to adhere by strong tendinous attachments to the edge of the pelvis, and so powerful is this adhesion that all attempts to pass the handle of a scalpel outwards between the fascia and the rami of the pubis and ischium uniformly fail.

In the posterior or anal division of the perineum the superficial fascia is little more than a cellular web, appearing, however, somewhat denser in the space between the tuber ischii and the anus; here its continuity with the subcutaneous cellular membrane of the gluteal region may be easily demonstrated, and it also dips in deeply into the ischio-rectal fossa, where its cells become inordinately loaded with fat. If the superficial fascia be carefully raised from before backwards, a deep process of this membrane may be seen to form a partition between the genito-urinary and the anal divisions of the perineum. The process referred to constitutes a septum, which, after dipping in deeply behind the transversi perinei muscles, becomes identified with the base of the triangular ligament of the urethra; to demonstrate this connection, however, requires some nicety of manipulation and a suitable subject. In raising this fascia the anatomist cannot fail to observe that its adhesion to the subjacent parts is everywhere extremely loose, except in the situations already specified.

The peculiar structure and the connections of the superficial perineal fascia afford a satisfactory explanation of the course which urinary effusions generally take in the living subject. When urine escapes into the perineum in consequence of rupture or ulceration of the urethra, provided the solution of continuity be seated superficial to the triangular ligament of the urethra, the liquid makes its way forwards to the scrotum, and after distending that part it proceeds upwards to the abdominal parietes, occasionally reaching the umbilicus, or even attaining to a higher level. The effusion rarely passes downwards along the thighs, or backwards to the neighbourhood of the anus, and its progress to the surface in the perineum is invariably tedious. In such cases the close adhesion of the superficial fascia to the rami of the pubis and ischium prevents the urine from reaching the thigh; the connection of the superficial fascia to the base of the triangular ligament of the urethra opposes its progress towards the anus; the density of the triangular ligament of the urethra impedes its passage into the pelvis; whilst the loose connection between the superficial fascia and the subjacent structures in front, the remarkable laxity of the dartos, and the continuity of this latter with the superficial fascia of the perineum on the one hand, and with that of the abdomen on the other, are so many circumstances inviting the stream to the scrotum, the penis, and the walls of the abdomen. The promptest treatment is demanded to remedy mischief such as has been described. A free division of the integuments and fascia in the perineum over the seat of rupture, for the purpose of giving the urine vent and putting a stop to further effusion, becomes indispensable, and without this measure all others must be unavailing.

The laxity of the superficial fascia as it approaches the scrotum should deter the surgeon from commencing his cutaneous incisions in the lateral operation of lithotomy too far forwards, lest urinary infiltration should ensue; and the density of the same structure in other situations indicates an early incision for the release of matter imprisoned beneath it.

For a description of the posterior or anal division of the perineum, including the ischio-rectal fossæ and the neighbouring fibrous membranes, the reader is now referred to the article Anus, where all the structures connected with the lower extremity of the rectum are described in detail. It should be borne in mind, however, that some branches of arteries (the inferior or external hemorrhoidal) pass across the ischio-rectal fossæ, entangled in the fat which occupies those excavations. The inferior hemorrhoidal vessels are usually three in number at each side; they derive their origin from the internal pudic artery, as it lies beneath the obturator fascia; their destination is the lower extremity of the gut and its appendages, and one of them (the most anterior) gains the front of the intestine to anastomose with a similar vessel from the opposite side, and with branches of the transversalis perinei also. The inferior hemorrhoidal vessels are remarkably tortuous and rather uncertain in their course; the anterior of them is sometimes divided in the lateral or bilateral operations of lithotomy, a circumstance which has led to this cursory notice of their anatomy.

When the superficial fascia has been displaced, many new parts become apparent in the genito-urinary division of the perineum; a quantity of loose adeps and also a very thin glistening fibrous expansion which adheres closely to the subjacent muscles and obscures the dissection, must, however, be carefully removed before the deeper structures are satisfactorily displayed. The central tendinous point of the perineum, the superficial perineal bloodvessels and nerves, the transversalis perinei artery with its accompanying veins and nerves at each side respectively, the urethra itself, still however obscured by the acceleratores urinæ muscles, the crura penis, each partly enveloped by the erector penis muscle, the transversi perinei muscles, and two small triangular spaces bounded by muscles and placed one at either side of the urethral prominence, are the principal objects which come into view.

The central tendinous point of the perineum is situated in the middle line, equidistant from the anus and the bulb of the urethra. It is a common point of insertion to many muscles; thus the superficial sphincter of the anus can be fairly traced to this spot, and so can many fibres of the acceleratores urinæ, the transversi perinei, the levatores ani, and Wilson's muscles. Here muscular fibres from opposite sides of the perineum become blended with each other; here, too, those from before and those from behind are intermixed, and some even descend from within the pelvis to identify themselves in this place with others which are subcutaneous.

The superficial perineal artery (the perineal artery of some anatomists), though not a large vessel, yet takes a lengthened and very regular course. Its origin is from the internal pudic artery at some little distance behind the transversus perinei muscle, whilst the parent trunk is still under cover of the obturator fascia; it immediately pierces that membrane, and likewise very generally passes through the base of the triangular ligament of the urethra. The artery next curves around the transversus perinei muscle lying on its superficial surface and running across its fibres. The vessel then inclines forwards and inwards through the triangular interval between the accelerator urinæ and the erector penis muscles, until at length it reaches the scrotum, and assuming the name of "the arteria septi," it terminates in a free anastomosis with the other arteries supplying the envelopes of the testicles. The superficial perineal artery lies deep posteriorly, but its position becomes very superficial as it approaches the scrotum; its branches are distributed freely to the muscles and integuments, and they likewise anastomose internally with branches from the corresponding artery of the opposite side, and externally with superficial branches from the thigh. Two veins accompany this artery; they are frequently dilated and tortuous in front, and in certain diseased conditions of the testicle or its coverings they sometimes form a complicated net-work in the scrotum.

The inferior or superficial division of the pudic nerve ("the perineal nerve" of many authors) follows pretty nearly the course of these vessels; like the artery, it is destined for the scrotum, where it terminates by several long and very fine branches, after supplying in its progress numerous twigs to the transversus perinei, accelerator urinæ, levator ani, and erector penis muscles. One very remarkable branch of this nerve (the bulbo-urethral of Cruveilhier) may be traced fairly into the bulb, whilst another (the external perineal of the same anatomist) runs superficially along the lateral part of the region, reinforcing and anastomosing with the perineal cutaneous branch of the lesser sciatic nerve.

The transversalis perinei artery is of small size; it springs from the internal pudic, a little anterior to the source of the superficial perineal artery, but these two vessels not unfrequently arise by a single common trunk. The transversalis perinei artery passes through the obturator fascia, and often perforates the base of the triangular ligament of the urethra; it quickly becomes superficial, applying itself to the cutaneous surface, and running usually near the posterior edge of the transversus perinei muscle, it thus gains the central tendinous point of the perineum, where it anastomoses with the inferior hemorrhoidals from behind, the transversalis and superficialis perinei arteries from the opposite side, and with the neighbouring superficial perineal. This vessel is accompanied by two veins and by one or more branches of the superficial division of the pudic nerve.

The accelerator urinæ muscle (the ejaculator seminis of some anatomists, the bulbo-cavernosus of others) extends from the central tendinous point of the perineum forwards along the urethra, being identified with the corresponding muscle of the opposite side in a raphé which occupies the middle line; and so intimate is this connection that both might be conveniently described together as a single muscle. The fibres of the accelerator urinæ spring from the side of the raphé, and pass from thence outwards and upwards upon the urethra. The anterior fibres incline very obliquely forwards and outwards to arrive at the surface of the corpus cavernosum penis, where they terminate. In consequence of this disposition the acceleratores urinæ muscles are separated from each other in front by a Y-shaped interval in which the urethra appears. The succeeding fibres, after embracing the urethra laterally, are lost on a short horizontal tendon, which likewise receives the corresponding fibres of the opposite muscle. This tendon is placed above the urethra, beneath the junction of the crura penis, and anterior to the triangular ligament of the urethra. The posterior fibres incline outwards more than the others, and are inserted into the superficial surface of the triangular ligament of the urethra, many of them extending nearly to the crus penis. The accelerator urinæ muscle lies on the bulb and the neighbouring portion of the corpus spongiosum. In conjunction with its fellow it constitutes a fleshy sheath, all but perfect, for the urethra. Its action is to compress the canal, and at the same time to draw forwards the bulb. It is employed in expelling the semen and the last drops of urine from the sinus of the bulb; and by contracting spasmodically it may even arrest the progress of a catheter, an occurrence explained by the manner in which many of its fibres completely surround the passage.

The erector penis muscle (called sometimes "the compressor penis," or "the ischio-cavernosus,") is placed obliquely along the lateral margin of the genito-urinary division of the perineum, where it partially envelopes and conceals from view the corresponding crus penis. It is elongated, broader in the centre than at the extremities, and curved so as to embrace the crus on which it is moulded. The erector penis springs by a narrow tendinous attachment from the inner surface of the tuber ischii, and from the extremity of the great sciatic ligament beneath the transversus perinei muscle; the fleshy fibres soon succeed, and after continuing in an oblique direction upwards, forwards, and inwards, they end in a fibrous expansion which inclines outwards and forwards to terminate by two processes on the surface of the corpus cavernosum penis. Anatomists are not agreed on the action of this muscle: it may serve to draw down and to compress the crus penis, and in that manner to influence the circulation therein, but it can have no direct concern in causing the erection of the organ.

The transversus perinei muscle ("the ischio-perineal" of some anatomists) passes from the tuber ischii to the central tendinous point of the perineum; in this course the muscle inclines forwards and slightly downwards, so that its direction is not exactly transverse. It is attached externally to the inside of the tuber ischii, above the origin of the erector penis and the crus penis; and internally it is confounded with the several muscles already specified as reaching the central tendinous point. The transversus perinei is often of a triangular shape, the base at the ischium, and the apex at the central tendinous point of the perineum; it is mostly fleshy, except at its insertion, which is aponeurotic. This muscle is exceedingly uncertain as regards its developement, being sometimes replaced by a few scattered fibres derived apparently from the levator ani, and occasionally reinforced by a second muscle, termed the transversus perinei alter. The transversus perinei alter, when present, lies anterior and superior to the other, and extends from the ramus of the ischium to the bulb, where it becomes confounded with the accelerator urinæ. The transversus perinei is related by its superficial surface to the superficial perineal fascia, the superficial perineal and the transverse perineal vessels and nerves, the insertion of the superficial sphincter ani, and the origin of the erector penis and the crus penis. Its deep relations are the levator ani and Wilson's muscles, together with the triangular ligament of the urethra. The transversus perinei contributes to the strength of the perineum by raising and fixing the central tendinous point; it also assists the levator ani in raising and supporting the rectum and the pelvic viscera. The transversi perinei muscles have been by some described as a single digastric muscle, semilunar in shape, and with the concave margin directed backwards and upwards towards the gut; the result of the simultaneous action of these two bellies would be to raise and compress the intestine in front, and thus to assist in completing the process of defæcation.

The triangular spaces are situated one at either side of the urethral prominence; each is bounded internally by the accelerator urinæ and the urethra, externally by the erector penis and the crus penis, posteriorly by the transversus perinæi, which constitutes the base of the triangle, whilst the apex is in front where the crus penis and the urethra unite. These spaces are small in the natural condition, but when carefully dissected they become very distinct; the superficial perineal vessels and nerves traverse them from base to apex; by separating the accelerator urinæ from the erector penis the anatomist obtains a view of the triangular ligament of the urethra between these muscles, and he may also form some estimate of its thickness and strength by the touch.

When the muscles and other structures belonging to the same layer of parts have been removed, the crura penis along the sides of the region, the urethra in the centre, and the triangular ligament of the urethra stretching across the arch of the pubis, are brought fairly into view; still further back, in the middle line, the recto-urethral triangular space may be partially seen, and also some fibres of the levator ani muscle descending to their insertion from behind the triangular ligament.

It is unnecessary in this article to describe the crura penis minutely. Each crus adheres to the rami of the ischium and pubis, becoming gradually thicker and larger as it approaches the symphysis, and at length the two crura unite to form the body of the penis; the lateral margins of the triangular ligament of the urethra, and the great pudic vessels and nerves in the last part of their course, are overlapped by the crura as they ascend.

The anatomy of the urethra in respect to catheterism has received the fullest consideration already, but the position of the bulb may be now again studied with advantage. This body lies in front of the triangular ligament of the urethra, and projects backwards and downwards towards the rectum; it is situated about one inch from the anus, and scarcely more than half that distance from the anterior wall of the intestine; yet the narrow interval between the bulb and the rectum constitutes a portion of the recto-urethral triangular space, through which the early incisions in the bilateral operation of lithotomy are carried. The bulb is retained in its position by a thin expansion derived from the anterior layer of the triangular ligament, and continuous with the membrane which invests the corpus spongiosum urethræ.

The triangular ligament of the urethra ("the deep perineal fascia" of some anatomists, "the perineal ligament" of M. Carcassone, "the middle perineal aponeurosis" of M. Blandin) presents itself next for examination. To expose the superficial surface of this ligament it is only further necessary to detach the crura penis from the bones and to free the bulb from its connections, but to exhibit the deeper surface satisfactorily the dissection must be conducted from within the pelvis. The triangular ligament of the urethra extends from the rami of the ischium and pubis at one side to the corresponding edges of bone on the other; its superficial surface, directed forwards and downwards, is in contact (so long as the parts remain in situ) with the crura penis, the bulb of the urethra, and the muscles already specified; its posterior surface, directed upwards and backwards, is related to the prostate gland, the membranous portion of the urethra, Wilson's muscles, and the levatores ani; its base, directed downwards and backwards towards the rectum, gives attachment to the deep process of the superficial perineal fascia, and presents a double curvature, being prolonged in the middle line into a peak, which adheres to the central tendinous point of the perineum; its apex corresponds to the lower extremity of the symphysis pubis, and includes the sub-pubic ligament between its laminæ, whilst its lateral margins adhere firmly to the rami of the ischium and pubis, and are distinctly continuous with the obturator fascia on either side. The opening which affords a passage to the urethra is situated about half an inch or rather less above the base of this ligament, and nearly one inch beneath the symphysis pubis, whilst that which transmits the dorsal veins of the penis is placed immediately below the sub-pubic ligament. The triangular ligament possesses uncommon strength; it serves to fix and to strengthen the urethra and to fill up the arch of the pubis, completing the walls of the pelvis where the bones are deficient, and thus supporting powerfully the abdominal and pelvic viscera. It constitutes a perfect partition between the superficial and the deep structures in the perineum, dividing the genito-urinary portion of this region into two distinct compartments; and it consists of two laminæ inseparably united to each other in some places, not so in others, for Cowper's glands, the sub-pubic ligament, the arteries of the bulb, the internal pudic vessels in a part of their course, and the so-called muscles of Guthrie, are developed between its layers.

Cowper's glands may be displayed by the careful removal of the superficial layer of the triangular ligament; they are two small greyish bodies, each resembling a pea in shape and dimensions, and placed one on either side behind and above the bulb, beneath the membranous portion of the urethra, and between the laminæ of the triangular ligament. Their ducts, which open into the urethra in front of the bulb, have been already described.

Guthrie's muscles, two in number, are situated (according to their discoverer) between the layers of the triangular ligament; each of them, as described by him, arises narrow and tendinous from the descending ramus of the pubis near its junction with the ischium, and becoming fleshy it passes tranversely inwards, and soon divides into two fasciculi, of which one spreads out on the upper surface and the other on the lower surface of the membranous portion of the urethra. In this manner the muscles from opposite sides meet in a tendinous raphé on the middle line of the urethra both above and below, the superior raphé being prolonged from the prostate gland to the junction of the crura penis, and the inferior raphé extending from the prostate to the bulb. Viewed either from above or from below, these muscles are fan-shaped, appearing expanded at the urethra and contracted at their origin from the bone, and they are believed to have the power of compressing the urethra so as to close the canal. Notwithstanding the accurate descriptions of Mr. Guthrie, many excellent anatomists have failed to demonstrate the exact arrangement of fleshy fibres which he has remarked, but the majority incline to the opinion that the peculiar reddish material in question is of a muscular nature.

The arteries of the bulb (one at either side) spring from the internal pudic after those vessels have arrived at the triangular ligament of the urethra, and whilst they are overlapped by the crura penis. Interposed between the laminæ, and situated about a quarter of an inch above the base of the triangular ligament, the artery of the bulb runs nearly transversely inwards, and near the urethra divides into two branches, of which one is small and destined for Cowper's gland, whilst the other is of large size and perforates the bulb to supply the corpus spongiosum urethræ. The arteries of the bulb are of considerable magnitude, particularly after puberty, so that they bleed profusely when wounded; they retract between the layers of the triangular ligament when divided, and this added to the narrowness of the perineum in front, and to the distance from the surface at which they are placed, renders it difficult for the surgeon to secure their cut extremities or otherwise to control their hemorrhage. The consequences of such an accident may prove speedily fatal; extreme care must therefore be taken to protect these vessels from the knife during lithotomy.

The artery of the bulb is endangered in the second period of the lateral operation whilst the surgeon cuts into the membranous portion of the urethra to lay bare the groove of the staff. The knife should be introduced into the urethra behind the bulb, and below and behind the course of the artery, and little or none of the triangular ligament except the posterior lamina where it invests the membranous portion of the urethra, should be divided in this incision, for the vessel requiring protection lies about one quarter of an inch above the base of the ligament, and therefore none but the very lowest fibres of that structure can be cut with impunity; in short the incision must be made into the membranous portion of the urethra as it lies behind the triangular ligament, and the bulb must be studiously avoided. Irregularities in the direction of these arteries calculated to embarrass the operating surgeon are occasionally encountered; arising sometimes prematurely from the pudic, they ascend very obliquely to the bulb; and again, although given off from the pudic at the usual place, they now and then take a curved course to their destination, the convexity of the curvature looking downwards and backwards; when either of these varieties occurs, the vessels in question run much closer to the base of the triangular ligament than usual, and are therefore imminently endangered in lithotomy.

The internal pudic arteries in their third stage belong to the perineum. This stage commences where the vessel enters the pelvis at the lesser sciatic notch, and ends at the ramus of the pubis, where it divides into its terminating branches. Posteriorly the trunk of the internal pudic is (strictly speaking) placed outside the precincts of the perineum, being separated from the ischio-rectal fossa by the obturator fascia, but it runs so close to that part of the region, and sends so many of its branches through the intermediate partition to lose themselves in perineo, that its description may be here legitimately given. At the commencement of its third stage, the internal pudic is interposed between the obturator fascia and the obturator internus muscle, the muscle separating it from the bone, whilst the falciform process of the great sciatic ligament covers the artery inferiorly: in this situation it lies at a great depth from the surface, being upwards of an inch above the level of the tuber ischii, and at least two inches and a-half distant from the integument; it here also describes a slight curve inclining upwards, forwards, and inwards, towards the edge of the ramus of the ischium. In the latter part of its third stage the internal pudic artery insinuates itself between the laminæ of the triangular ligament, and after continuing thus for some distance it at length perforates the superficial layer, places itself between the crus penis and the ramus of the pubis, and there finally divides into the artery of the crus and the dorsal artery of the penis.

On entering the pelvis the pudic arteries of opposite sides are widely separated from each other, but in the neighbourhood of the pubis they gradually converge until their ultimate branches meet on the dorsum of the penis; their position likewise becomes more and more superficial as they proceed.

In the early part of its third stage the pudic artery is accompanied by the trunk of the internal pudic nerve, and afterwards for a short distance by both the branches of that nerve; but the deeper of the two (viz. the dorsalis penis) alone continues in relation with the artery in the latter part of its course. Two veins accompany the artery throughout.

The position of the internal pudic vessels exposes them to injury in the lateral operation of lithotomy; but if their relations be considered it will appear that the danger of hemorrhage from this source has been much exaggerated. The falciform process of the great sciatic ligament, the crus penis, the projecting edges of the bones, and the obturator fascia afford these vessels so much protection from below that the operator seldom wounds them in cutting into the bladder, nor is such an injury possible unless the edge of the knife be lateralized to an extreme degree; but if the knife be carelessly withdrawn from the bladder, they certainly incur considerable risk, for in that step of the operation a layer of fibrous membrane alone protects the vessels, and the convex edge of the instrument, if directed unduly outwards, might readily enough divide them. When such an accident has occurred, all attempts to tie the bleeding artery in the ordinary manner have usually failed, for so deeply do the pudic vessels run, and so firmly bound down are they by the triangular ligament and the obturator fascia, that the ligature, as commonly applied, has proved useless in the hands of even the most dexterous surgeons. The open mouth of the artery may, however, in such cases be often secured by the aid of a curved needle carried deeply into the wound, and some practitioners (amongst the number M. Roux) have succeeded by the same means in tying the pudic artery itself in the vicinity of the tuber ischii, a proceeding attended with complete success. The judicious application of pressure to the bleeding point by an apparatus so constructed as to plug the wound at the same time that it permits the urine to escape freely, has been also followed by satisfactory results. The same principles of treatment are applicable to hemorrhage from accidental wounds of the arteries of the bulb in lithotomy.

On dividing the triangular ligament of the urethra the dissector arrives at the deep compartment of the anterior division of the perineum, but to examine its contents with advantage he requires a section of the pelvis, such as that advised in a former part of this article. This compartment is limited superiorly or towards the abdomen by the recto-vesical layer of the pelvic fascia; inferiorly or towards the surface by the back of the triangular ligament of the urethra; and posteriorly by the rectum; its shape is somewhat triangular, and it contains Wilson's muscles, many fibres of the levatores ani, a part of the membranous portion of the urethra, the prostate gland, a plexus of veins excessively developed in some subjects, and at times also an irregular artery justly dreaded by the lithotomist.

Wilson's muscles (the compressores urethræ) are two triangular fleshy fasciculi, which arise from the back of the symphysis pubis, each by a narrow tendon; their point of attachment is about one-eighth of an inch beneath the anterior true ligament of the bladder, and the same distance above the lower margin of the cartilaginous arch of the pubis. The two muscles, expanding as they descend, separate from each other at the membranous portion of the urethra, and passing one on each side of that part of the canal they again unite beneath it in a sort of tendinous raphé, which extends from the prostate gland to the bulb; many of their fibres may be likewise traced to the central tendinous point of the perineum. A cellular interstice intervenes between the two muscles at their origin, and from the levatores ani they are separated at each side respectively by cellular tissue and some small veins. Wilson's muscles may elevate and compress the urethra so as to close the canal; their influence in catheterism is decided and has been already discussed; one of them, the left, is divided in the lateral, and both are cut in the bilateral operation of lithotomy. In some subjects Wilson's muscles are absent, or rather they are inseparable from the levatores ani; but in such cases the anterior fibres of these latter muscles surround the urethra, perform all the offices assigned to the compressores urethræ, and are similarly circumstanced as regards operations on the perineum.

The recto-urethral space, but partially seen so long as the triangular ligament of the urethra remains in situ, becomes fully exposed after the division of that fibrous septum. This space results from the inclination backwards of the lower extremity of the rectum, whilst the urethra inclines forwards through the arch of the pubis; its form is triangular, the base at the integuments of the perineum, the apex at the prostate gland, the membranous and the bulbous portions of the urethra constituting its anterior wall, and the rectum bounding it posteriorly. In cutting from the integuments to the urethra through the recto-urethral triangle, the anatomist encounters, first, the superficial perineal fascia; next, the extremities of the several muscles which meet and are confounded with each other at the central tendinous point of the perineum, and also the small arterial anastomosis situated in the same locality, still deeper the peaked prolongation of the triangular ligament; and, lastly, Wilson's muscles at their junction beneath the urethra.

The membranous portion of the urethra is situated within ten lines of the rectum, and the bulb projects still further backwards, lying but half an inch apart from that intestine, so that, in the lateral and also in the bilateral operations, the lithotomist incurs some risk of wounding the bowel as he lays bare the groove in the staff. In the bilateral method the operator endeavours, by a semilunar incision carried across the recto-urethral triangular space, to reach the staff as it lies in the membranous portion of the urethra, and from the proximity of the bulb to the rectum both these parts are endangered as the knife traverses the intermediate space. In the lateral method the rectum is not so likely to be injured in the corresponding step of the operation, because the bowel is further removed from the membranous portion of the urethra than from the bulb, and besides the urethra is incised somewhat upon its lateral aspect. In either case the surgeon best ensures the safety of the intestine by taking care to have the fæces evacuated before the operation commences, by holding the staff well up into the arch of the pubis, and by directing the point of the knife *forwards* as he cuts into the urethra.

The recto-urethral triangular space is the position usually occupied by that rare form of rupture, a perineal hernia; in this disease the hernia leaves the abdominal cavity at the bottom of the great cul-de-sac of the peritoneum, and drawing down the serous membrane in its progress it gradually insinuates itself between the prostate gland and the rectum, and at length protrudes between the rectum and the bulb. In the perineum the sac is in general rather superficial. The tumor occasionally deviates from the middle line, and projects outwards and backwards behind the transversus perinei muscle into the ischio-rectal fossa; it rarely undergoes strangulation, being in almost every instance reducible.

The prostate gland demands the special attention of the surgical anatomist, for much of the operator's success in lithotomy turns upon his knowledge of the relations, the size, and the density of this organ as well as of the resistance of its capsule. The prostate is heart-shaped; it has been also not unaptly compared to a chesnut. Its base, directed backwards and upwards, embraces the neck of the bladder, and usually presents a notch for the entrance of the ejaculatory ducts; its apex, truncated and directed forwards and downwards, is in contact with Wilson's muscles and separated from the triangular ligament of the urethra by an interval of less than half an inch; its under surface, grooved longitudinally in the middle line, looks somewhat backwards and rests upon the rectum with the intervention of a quantity of rather dense cellular tissue, in which fat never accumulates; its upper surface, inclining slightly forwards and less extensive than the lower, is connected to the pubis by the anterior true ligaments of the bladder; and its sides, which are rounded, are covered by the levatores ani muscles. The vesiculæ seminales are related to the base of the prostate gland, and the dorsal veins of the penis lie upon its upper surface, which is scarcely three-quarters of an inch distant from the pubis. The rectum, when empty, is in contact with the under surface only of the prostate, but when distended, it also encroaches upon the sides of the gland; this occurs to an extreme degree whenever the bowel presents the dilatation so commonly observed in elderly persons; in such cases the prostate appears embedded in the walls of the gut, a disposition fraught with danger to the intestine in the ordinary operation for stone.

The prostate gland varies so much in size at different periods of life, and even in different individuals of the same age, that it is impossible to specify its exact dimensions. The organ is small in the child; it increases greatly at puberty; in middle age its measurements are still larger, and in the decline of life they become not unfrequently excessive. In the healthy adult subject the extreme length of the prostate gland from base to apex may be estimated at from an inch and a quarter to an inch and a half; its depth at the base seldom exceeds one inch, whilst from side to side it measures somewhat more than an inch and a quarter. The urethra traverses the prostate from base to apex, and runs much nearer to the upper than to the lower surface of that body, so that the canal is very unequally surrounded by glandular substance. At the base of the prostate the glandular substance above the urethra varies from two to four lines in depth; below the canal it is upwards of six lines deep; laterally its thickness may be estimated at about eight lines, whilst in the direction of the ordinary incision in lithotomy, viz. downwards and outwards, from nine to twelve lines is the average measurement. Exceptional cases have been reported by Velpeau and others, in some of which no trace of glandular substance existed *above* the urethra, and in others little or none *beneath* it; the latter variety might lead to unpleasant consequences in lithotomy.

The prostate gland is enveloped by a dense capsule continuous with the fibrous membrane derived from the posterior layer of the triangular ligament of the urethra, and investing the membranous portion of that canal. This capsule is identified above with the anterior and lateral true ligaments of the bladder, and its strength is such as to impart great firmness to the prostate, and a power of resistance altogegether foreign to the glandular substance. The anatomist finds it extremely difficult to lacerate the prostate so long as the capsule retains its integrity, but a trifling force suffices to tear or to split the gland after it has been deprived of this covering. The strength of the capsule explains the difficulty experienced by lithotomists in dividing the prostate gland by the cutting gorget, and was doubtless in great measure the cause of those distressing accidents which so frequently resulted from the slipping of that instrument, and which have led to its disuse in latter years. The common ejaculatory ducts traverse the prostate gland from behind forwards and upwards; they are closely approximated to each other, and for practical purposes may be considered to occupy the middle line. It would be impossible to effect with certainty a median section of the gland in the living subject without injury to one or both of these ducts: this constitutes a strong objection to the recto-vesical operation of lithotomy, but they are out of danger in the lateral and bilateral methods.

The veins in the neighbourhood of the prostate gland and of the neck of the bladder are remarkable for their plexiform arrangement, and are called the vesico-prostatic plexus. This plexus, receiving anteriorly the dorsal veins of the penis after their entrance into the pelvis, and communicating posteriorly with the hemorrhoidal veins, delivers its blood into the internal iliacs; it lies chiefly upon the upper and lateral surfaces of the prostate, and on the lateral and inferior aspects of the neck and neighbouring portion of the base of the bladder. The veins which constitute this plexus are covered by a layer of the capsule of the prostate, and bound down to the bladder by a strong membrane derived from the recto-vesical lamina of the pelvic fascia. They communicate in the freest manner with each other, and are but moderately developed in young and healthy subjects, whilst in elderly persons and in cases of chronic disease of the bladder, as well as in calculous affections, they occasionally attain to an immense size and assume a varicose disposition. The hemorrhage from vessels so enlarged might be followed by a fatal result in lithotomy. The mouths of these veins remain permanently patent after they are divided; this results from the fibrous investment which binds them down, and has been supposed by the French surgeons to predispose them to phlebitis after operations, by exposing their delicate lining membrane to the irritating influence of the urinary stream.

An irregular artery is sometimes found along the side of the prostate gland, and has been the source of fatal hemorrhage when divided by the lithotomist. This vessel is destined to replace one or more of the terminating branches of the internal pudic, and when present, always continues on to form the dorsal artery of the penis; it occasionally gives off the artery of the bulb and the artery of the crus penis, or this latter branch alone, during its progress. When the irregularity now described occurs, the pudic artery of the same side suffers a corresponding diminution in size, and stops short in the perineum after furnishing a variable number of branches. The irregular trunk here alluded to springs in general from the internal iliac, or from one of the branches of that artery; but from whatever source derived, it runs along the side of the prostate gland to the neighbourhood of the pubis, where it mounts above the urethra and passes beneath the symphysis, in company with the dorsal veins of the penis. This irregular vessel runs nearly in the line of the incision in lithotomy, whether performed according to the lateral or the bilateral methods, and pursuing such an unfortunate course it can rarely escape the knife during these operations. Examples of this irregularity have been recorded by Blandin, Velpeau, Shaw, and others.

The preceding description of the deep compartment of the perineum would be imperfect without some application of the anatomy of that space to practical purposes, particularly as the third incision in the lateral operation of lithotomy is performed within its limits. In this step of the operation the surgeon, in order to make way for the calculus, cuts through the remainder of the membranous portion of the urethra, together with the left lobe of the prostate gland, and in doing so he must also divide Wilson's muscle and some fibres of the levator ani. From the many important parts which surround the prostate, this incision is beset with difficulties. The rectum is much endangered; this arises from its proximity to the under surface of the prostate gland, and from its occasional dilatation. To insure the safety of the gut it should be emptied by the administration of an enema previous to the operation; the handle of the staff should also be depressed before the third incision commences, and the edge of the knife should be duly lateralised; without the latter precaution all other expedients to save the intestine are useless. The depression of the handle of the staff raises the beak of the instrument behind the pubis, and causes the knife to enter the bladder as much as possible in the axis of that viscus, a line of incision best calculated to protect the bowel; and by performing this manœuvre at the proper moment the operator raises the prostatic portion of the urethra from the rectum, thus contributing still further to the security of the gut.

Hemorrhage is the most formidable consequence of the third incision in lithotomy. The pudic artery incurs a certain amount of risk when the operator, in his anxiety to save the rectum, directs the edge of the knife too much outwards, but from a former part of this article the reader may perceive that such an accident is of rare occurrence. The irregular artery which runs along the prostate is much more to be dreaded, for the surgeon can neither foresee nor avoid the danger, and from its position all attempts to tie the vessel when wounded must necessarily prove fruitless, whilst the absence of a resisting surface beneath the bleeding orifice prevents the plug from commanding the hemorrhage.

A profuse loss of blood from the vesico-prostatic plexus of veins may be also encountered, and is most likely to happen in elderly persons. The largest of these vessels are situated at the neck and along the base of the bladder, so that the surgeon guards against such a casualty most effectually by confining his incisions as much as possible within the limits of the prostate gland.

The French writers consider phlebitis and diffuse cellular inflammations to be the most common causes of death after lithotomy, and they attribute both these fatal affections to an incision carried beyond the base of the prostate. They maintain that the cut surface of the gland is sufficiently tough and resisting to bear the urine with impunity, and that the lax cellular membrane around the neck of the bladder, and the veins in the same locality, speedily inflame when irritated by that secretion. In Paris the bilateral operation is therefore mostly practised, as it gives the largest incision practicable within the circumference of the prostate gland, at the same time that it protects the common ejaculatory ducts, the rectum, and the pudic artery from injury.

In these countries the lateral method is still generally preferred, whether it be that British surgeons usually find a section of one side of the prostate sufficient for the extraction of the calculus, or that a moderate division of the neck of the bladder in their hands seldom leads to the above described unfortunate results, particularly if a ready outlet for the urine be ensured by a free section of the superficial structures.

In the bilateral operation a double risk of wounding the irregular dorsal arteries of the penis must be incurred; and should the blades of the lithotome, in consequence of a misconception of the width of the prostate gland or of the transverse measurement of the bony boundary of the perineum, be too widely divaricated, a twofold liability to venous hemorrhage and to injury of the rectum will be the result, and the pudic vessels on both sides will be endangered,—accidents which demand due consideration from the practitioner in weighing the relative merits of these rival operations.

In dividing the prostate gland the knife is apt to slip from the groove of the staff by reason of the great toughness of the capsule, and to pass between the rectum and bladder, causing extreme mischief. When this part of the operation is performed with the simple knife, the lithotomist guards against such an unpleasant accident by incising the membranous portion of the urethra *freely* before he commences the third incision, and by depressing the *handle* of the knife considerably as he pushes its *blade* onwards to the bladder; by the former precaution he makes certain that the point of the knife is properly lodged in the groove of the staff, and by the latter that it follows the groove fairly into the bladder. Some excellent instruments have been devised to prevent the occurrence of so serious an accident, but to describe them here would be too wide a digression.

The lithotomist is liable to commit other mistakes still in the same stage of the lateral operation. His incisions may fall short of the bladder altogether, leaving the prostate insufficiently divided; or he may, on the other hand, transfix the bladder by plunging his knife too deeply. The former error may lead to disappointment in extracting the stone, and to severe injury of the neighbouring parts in the attempt to do so; it admits, however, of correction if discovered in time, but the latter mistake must be irreparable. Occurrences such as these result from an imperfect knowledge of the depth of the perineum, and may be accounted for by the great variation in this respect which the region presents in different subjects. Dupuytren and Velpeau found the distance from the neck of the bladder to the integument of the perineum to vary in different cases to the extent of two inches and upwards, the disparity depending chiefly on the degree of obesity of the individual.

The deep compartment of the anterior division of the perineum has claims upon the attention of the practical surgeon independent of lithotomy. Matter sometimes forms within this space, and from the contiguity of the rectum on the one hand, and of the urinary organs on the other, such collections produce most distressing symptoms. The triangular ligament of the urethra prevents the abscess from gaining the surface directly, so that at length it either bursts into the rectum or makes its way gradually behind the base of the ligament. The finger introduced into the gut affords satisfactory information as to the nature of such cases, and free incisions through the perineum are followed by the most marked relief.

Effusions of urine from accidental ruptures of the urethra occur less frequently behind the triangular ligament than in front of it, for in the former situation the canal is so thoroughly protected by its deep position that contusions inflicted upon the surface of the region but rarely affect it. False passages from the forcible introduction of instruments take place in general anterior to the triangular ligament; but when the urethra gives way behind a stricture in consequence of violent expulsive efforts of the bladder, the urine sometimes escapes into the deep compartment of the perineum, and destructive consequences are sure to ensue unless counteracted by timely treatment.

Prostatic diseases are attended by a train of symptoms which depend upon the sympathies of neighbouring organs. When the gland suppurates (not an uncommon consequence of acute inflammation), the matter usually discharges itself by the urethra, the tough capsule determining its route; but at times the abscess bursts into the rectum, or it may even point in the perineum after passing behind the base of the triangular ligament.

(Robert Mayne.)

PERITONEUM.—The serous membrane of the abdomen, investing the inner surface of the abdominal walls and the outer surface of the abdominal viscera, and forming, by duplication, sheets with both surfaces free, called omenta, mesenteries, suspensary ligaments, &c.

The peritoneum of the male subject, in accordance with the rule of serous membranes, is a shut sac: in the peritoneum of the female the single exception to this rule is met with: here the Fallopian tubes open into the peritoneal cavity, and their mucous surface is continuous, through their fimbriated extremities, with the serous surface of the peritoneum. Another circumstance that renders the female peritoneum peculiar amongst serous membranes is, that it is necessarily ruptured in the occurrence of a normal process, namely, in the escape of an ovum.

The manner in which a single serous shut sac, by a kind of intus-susception, invests the external surface of viscera and the internal surface of the cavity in which they are contained, is admirably illustrated by the well-known comparison of a double night-cap. Where the cavity contains only a single viscus of a simple rounded form, as, for instance, the pericardium containing the heart, the comparison is very apt. But when, as in the case of the abdomen, numerous viscera of irregular shape are contained in the cavity, the matter is much more complicated, and the resemblance, therefore, far less striking. Yet is the relation of the parietal part of the peritoneum to the visceral part, and of both to the abdominal viscera, essentially similar to that indicated in this well-known simile. The complexity of the peritoneal folds seems mainly to depend upon a strict adherence to such a simple relation, in the case of each of a great number of viscera, with their vessels, &c. contained in a single cavity. Each viscus, whatever its shape, whether closely or loosely connected, must have its arteries, its veins, its nerves, and its lymphatics passing to and from it, and the whole must be invested by a single shut sac without loss of continuity. The complexity thus arising demands for this membrane a lengthened description.

We propose, first, to trace its continuity throughout its entire extent; next, to describe the sheets with two free surfaces, which it forms by duplication; thirdly, to examine the manner in which it invests each of the viscera, and the abdominal parietes, that is to say, the extent to which it does so in the case of each, the point at which it arrives at and quits each, and so on; and, lastly, to describe its connexions, or the adhesion of its external surface, varying in intimacy, with the parts which it invests. The most important points connected with the anatomy of the peritoneum will be incidentally involved in the consideration of the first of these propositions.

Continuity of the peritoneum.—To demonstrate the unbroken continuity of the peritoneum, we are compelled, in description, to trace it in various directions, starting from a certain point and following it up till, having performed a complete circuit, we return again to our starting point. In doing so we shall avoid restricting ourselves to the mesial or any other sectional line. We believe that such a restriction, closely adhered to, tends to convey an erroneous impression, namely, that of a line instead of a superficial expanse. In thus tracing the peritoneum, it is better to let the mind rest upon the idea of a free surface, rather than upon that of a membrane. By a membrane one is apt to understand a separable skin; but in some situations not only is it impossible, by any ordinary manipulation, to separate the peritoneum from its connections, but two layers of it often form together a structure so thin that one can hardly help regarding it as a single membrane. In no instance is any part of a serous membrane free on both its surfaces. The external surface of the peritoneum, like that of all other serous sacs, is every where adherent, either to the subjacent structures, or, as in its duplications, to itself; whilst, on the other hand, its internal surface is, normally, every where free. It follows then, that wherever, in the peritoneal cavity, the finger can be placed on a free surface, there is a layer of peritoneum immediately beneath it; that if a continuous free surface is demonstrated, the continuity of the serous membrane is proved; that in fact a free serous surface represents a layer of serous membrane, and may be described instead of it when continuity alone is sought to be proved. We shall therefore at present use the expressions free surface and layer of serous membrane as synonymous; the free surface of a viscus instead of the serous membrane investing a viscus.

When the abdominal cavity is laid open in front by a crucial incision, the inner surface of the reflected flaps is seen to be free, glistening, and of a pale red colour. By a slight examination of the cut edges this is found to be the free surface of a membrane, whereof the other surface is connected to the subjacent structures by areolar tissue: the free surface is the parietal serous surface of the abdomen: the membrane is the parietal portion of the peritoneum. If an incision has been carried from the navel to the xiphoid cartilage, a falciform, membrane-like process, strikingly resembling the frœnum linguæ, is seen connected with the anterior parietal peritoneum, a little to the right of the middle line, projecting backwards, and towards that aspect presenting a free concave border. It is the falciform ligament of the liver. The base or broadest extremity of the falx is sessile along an antero-posterior line upon the upper surface and anterior edge of the liver; which line corresponds with and runs into the great antero-posterior fissure on the under surface of the liver; and this fissure receives the round ligament, and consequently the free edge of the falx which encloses it. The apex of the falx is at a point on the inner surface of the anterior abdominal parietes, corresponding to the navel. The surfaces of the falciform ligament are continuous with the serous surfaces of the parietes and liver; its free border, as incidentally mentioned above, encloses a structure called the round ligament of the liver, which gives a considerable thickness to this part.

The round ligament of the liver is the umbilical vein of the fœtus, degenerated to a fibrous cord in the adult, and it runs across, as that vein did, from the navel to the antero-posterior fissure of the liver, defining the free border of the falciform process in question. The composition, then, of the falciform ligament of the liver is—a portion of peritoneum doubled or folded, so that its outer surface is brought in contact with itself, as happens when a sheet of paper is folded so as to make two leaves. The two surfaces thus brought into contact, are united together by areolar tissue, as if the two leaves were stuck together with paste; and the round ligament lies along in the extreme edge of the fold, like a string that holds a sheet of two leaves in a book-cover. The vessels necessary for the nutrition of these structures ramify in the interposed areolar tissue. It seems as if the umbilical vein, in making the shortest route from the navel to the longitudinal hepatic fissure, had carried back before it a fold of the superjacent peritoneum.

We have spent more time in describing this, the first peritoneal fold we have come to, than is due to its importance, because it affords us, that which we want in this early stage of our description, an instance of the manner in which the peritoneum invests the various organs, having the advantage of extreme simplicity. A bowel is invested by the peritoneum and it occupies a situation in a fold precisely analogous to that which the round ligament occupies in the falciform ligament; whilst the vessels and nerves of the bowel pass to and from it imbedded in the areolar tissue uniting the apposed surfaces.

Placing a finger of each hand on each side of the falciform ligament of the liver, they may both be slipped along on the free surface of the anterior parietal portion of the peritoneum in a direction at first upwards, then slanting, then backwards, until they are each of them arrested in a corner, or cul-de-sac. They have passed along first on the peritoneal lining of the anterior abdominal muscles, and afterwards on that of the diaphragm. They are now arrested from being slipped along any further in the same direction by the peritoneum leaping across, or extending across, from the lower surface of the diaphragm to the upper surface of the liver. In order to pass them along any further on the peritoneal surface they must be carried off laterally or slipped downwards over the upper surface of the liver. We will pursue the latter course. The corners, or cul-de-sacs, in which we suppose the fingers to rest, are those formed by the falciform ligament, the liver, the diaphragm, and the coronary ligament all meeting together: the latter is the name given to that portion of the peritoneum which extends across between the diaphragm and the liver.

First, then, let the finger which is placed on the left side of the falciform ligament be slipped down over the upper surface of the left lobe of the liver, round its anterior edge, and backwards along its inferior surface; it will be arrested by a membraniform sheet extending across from the fissures of the liver to the lesser curve of the stomach, called the lesser or gastro-hepatic omentum. There for the present we leave it, and now let the other finger be in like manner passed down over the upper surface of the right lobe of the liver, around its anterior surface, and backwards along its under surface, either over the gall-bladder or to the right of it: behind the neck of the gall-bladder, by giving it a direction inclining towards the left, it may be slipped behind the same sheet as arrested the other finger; that is to say, it may be brought to rest upon the posterior surface of the lesser omentum, upon whose anterior surface we left the other finger. This position it gains by being slipped along on the narrow isthmus of liver called lobulus caudatus situated behind the portal fissure, in doing which it passes through a kind of foramen, called the foramen of Winslow, whereof the lobulus caudatus is the superior boundary. The inferior boundary of this so-called foramen is formed by the duodenum; the posterior by the vena cava; and the anterior by the vena portæ, the gall-duct, and the hepatic artery. These are the organs and vessels which surround the foramen of Winslow: they are, however, all covered by peritoneum in such a manner that the finger passed round the foramen, which is about one inch in diameter and of a somewhat semicircular form, glides around on a continuous circle of peritoneum.

The free surface of the lower aspect of the right lobe of the liver has been seen to extend, through the foramen of Winslow, along the lobulus caudatus; the continuity of surface of course extends to the lobulus Spigelii, from whence it may be traced towards the left and forwards to the posterior aspect of the lesser omentum, and backwards to the posterior abdominal parietes.

The finger being placed on that part of the peritoneum which covers the right kidney, it may be made to glide along the free surface up to the posterior boundary of the foramen of Winslow, and into the foramen itself, which demonstrates the peritoneal continuity in this direction. In much the same way the finger may be slid along on the duodenum until it is thereby conducted into the foramen.

With regard to the continuity of the peritoneal surface of the anterior boundary of the foramen of Winslow, if the finger be placed on the anterior surface of the lesser omentum and slid along on it towards the right, it comes to a free edge thickened by the vessels and duct mentioned above; doubling around this edge it may be made to glide into the foramen; thus demonstrating that the anterior and posterior surfaces of the lesser omentum are continuous with one another around the vessels and duct that thicken its free border and form the anterior boundary of the foramen of Winslow.

Now since, as we remarked above, a free peritoneal surface always indicates a layer of peritoneum, the lesser omentum having two free surfaces consists of two layers; and its two surfaces being continuous around the vessels mentioned, its two layers are continuous in like manner. It, therefore, is a portion of peritoneum doubled or folded upon itself, enclosing vessels and a duct in the extremity of the fold; just as we saw was the case with the falciform ligament enclosing, in the extremity of its fold, the obliterated umbilical vein.

When a double peritoneal sheet passes across from one bowel to another, or from the parietes to a bowel, it is described as attached along the lines where it first lights upon or comes in contact with such parts. Speaking in such a way, the lesser omentum is attached to the liver and stomach by the whole extent of its borders, except that small portion between the duodenum and porta which is free: and in fact this border is said to be free only because that which it encloses is small; if the gall-duct were an inch in diameter, the right border of the lesser omentum would be said to be attached to the gall-duct. Disregarding at present the last observation; the line of attachment, then, of the lesser omentum is continuous all around except at its free border. Let us trace this line of attachment from the porta of the liver to the pyloric end of the stomach in the circuitous direction in which alone it can be done. From the porta, then, we trace this line along the posterior half of the antero-posterior fissure of the liver, inclining a little to the left of this fissure so as to reach the cardiac end of the stomach, and thence along the lesser curvature of the stomach to the pylorus.

The gastric attachment of the lesser omentum is placed transversely, whilst its hepatic attachment runs antero-posteriorly, with only a moderate inclination from side to side, so that this omentum has a kind of twist.

It seems as though the gall-duct in gaining the shortest route from the liver to the duodenum had carried out the superjacent peritoneum from the cardia and lesser gastric curvature into a fold, as far out as the position of the straightest line from the porta to the pylorus; that this fold would have projected in the middle line, but that the enlargement of the right lobe of the liver displaced its posterior part with the cardia to the left, whilst the duodenum being brought into adhesion with the posterior abdominal walls displaced its anterior part to the right, and that both displacements have resulted in an almost transverse instead of an antero-posterior horizontal direction. In many vertebrate animals, especially those below the class Mammalia, the duodenum is not adherent to the posterior abdominal parietes, and the pylorus as well as the cardia is frequently in the middle line, whilst the two lobes of the liver are of pretty equal transverse extent; in such cases the lesser omentum extends antero-posteriorly in the middle line, (*figs.* 490, 491,) and this, we consider, is its typical position. This point will be more fully considered when we come to a particular description of the omenta; at present we are endeavouring to demonstrate the continuity, merely, of the peritoneum throughout: it is the existence of the omenta, or rather their distorted position in the human subject, that renders this demonstration so difficult.

It is necessary at this stage of our description to study the peritoneal sheet, or bag, with two free surfaces, called the greater omentum. On making an incision, as above, through the abdominal parietes, the liver and stomach are at once brought into view; but the small intestines are concealed by the great omentum covering them in front. It is a membraniform apron, having plentiful reticulations of vessels, and often loaded with fat, especially near the vessels. Viewing it undisturbed it appears to be pendent from the greater curvature of the stomach, and to have a free inferior border touching, usually, the pelvic region; but on lifting it up and looking at its posterior aspect, it is seen to be attached also to the transverse portion of the colon, which at once informs one that it is double. The fact of its being double, however, may be much more strikingly demonstrated in the following manner. If a catheter be held in the foramen of Winslow, and air be blown through it, the great omentum (provided there be no abnormal breach of continuity or adhesion in it) will become inflated like a great bladder; the inflation extending, not only downwards below the greater curve of the stomach, but to the left beyond its fundus, and also to the lesser omentum. The cavity so inflated is called the sac of the omentum, or the posterior cavity of the peritoneum, and the foramen of Winslow is the orifice that leads to this sac—the neck that connects together the anterior and posterior cavities of the peritoneum, making them one.

The foramen of Winslow is not generally big enough to admit more than one or two fingers to be passed through it; but an incision being made through the lesser omentum, the hand may be introduced into the omental sac and passed downwards behind the stomach and in front of the transverse colon, until it reaches the lowermost extent of the great omentum, or bottom of the great omental pouch; it will thus be between the two layers of what we considered like a double apron, but which, rather, is a pouch. The hand may now be carried in either lateral direction until it is arrested by the sides of the pouch, which correspond, on the right with the point where the colon crosses the duodenum, and on the left with the point where the colon, from being transverse, becomes descending,—that is to say, the sides of the pouch hang down from these points. Above the latter point, the hand may be carried towards the left, beyond the fundus of the stomach and somewhat behind the spleen, where it will be arrested by an attachment to the posterior parietes, the line of which extends from the cardia to the left bend of the colon.

There is, therefore, a great pouch of peritoneum, the inside and outside of which are both free; and consequently it has an internal or lining layer and an external layer; we will presently show how these are continuous with each other and with the peritoneal investments of surrounding parts. The left side of the mouth of this pouch is carried up into a long corner reaching the cardia; its continuous line of attachment extends from the cardia along the greater curvature of the stomach to the pylorus; then along a small extent of the duodenum till it reaches the transverse colon; next along the transverse colon to its left bend, and thence along on the posterior abdominal parietes of the left hypochondriac region, or rather over the left kidney, to the cardia whence we started. The spleen is sessile upon the external surface of this bag to the left of the fundus of the stomach. That portion of it which intervenes between the stomach and colon is called the great omentum, and that portion which is situated to the left of the fundus of the stomach is called the splenic omentum.

We may now return to our demonstration of the continuity of the peritoneum by tracing its free surface as before. The two surfaces or layers of the lesser omentum were seen to be continuous around the vessels enclosed in its free right border, at the foramen of Winslow. These two layers, as yet adherent, separate at the lesser gastric curvature, invest the stomach —one behind and the other in the front—meet again, and again adhere along the fundus and greater curvature, forming a sheet with two free surfaces, which to the right extends to the spleen and abdominal parietes, and downwards to the transverse colon; that part of it, however, which intervenes between the stomach and colon is bagged out or excessively widened so as, in ordinary circumstances, to hang down in a pouch as low as the pelvis. Having reached the front of the transverse colon, the layers again separate to invest it—one above and the other below—meet again on its posterior aspect, and again adhering together form the transverse mesocolon, which extends from the colon to the posterior abdominal parietes, where having arrived they finally separate, partially investing, as they do so, the transverse portion of the duodenum. Thus both layers reach the abdominal parietes along the continuous line of attachment of the splenic omentum and the transverse mesocolon; the internal layer from this continuous line invests the pancreas and other parts behind the stomach, then the lobulus Spigelii, and thus is conducted to the posterior surface of the lesser omentum, from which we started. The external layer of the omental sac, having reached this line of parietal attachment as part of the splenic omentum to the left, passes off on the left kidney and the lateral abdominal parietes and diaphragm; having reached it below as the transverse mesocolon, it may thence be traced downwards to the root of the mesentery.

The small intestine is enclosed in the extremity of the fold of a duplicature of peritoneum. That part of the fold which extends across from the posterior parietes to the intestine is called the mesentery. The two component layers of the mesentery are adherent by their apposed surfaces, except where vessels, &c. intervene, so that it is a parieto-visceral sheet with two free surfaces. The parietal attachment of the mesentery is called *its root*, and extends obliquely across the spine from the left side of the second lumbar vertebra, where the duodenum emerging from the root of the transverse mesocolon becomes jejunum, to the right iliac fossa, where the ilium enters the cœcum. Though the parietal attachment or root of the mesentery is but a few inches in length, its visceral attachment by means of numerous ample foldings, like a ruffle, corresponds in length with the twenty feet of small intestine. Tracing, then, the peritoneum heretofore forming the external layer of the great omental sac from the point where it reaches the posterior parietes as part of the transverse mesocolon, downwards, we come to that side of the root of the mesentery which looks upwards and to the right; thence we trace this surface continuous along the mesentery, over the bowel, back again along the other side of the mesentery, so reaching that side of its root whose aspect is downwards and to the left; in both which directions the peritoneum may be traced onwards. To the left it reaches the right side of the descending colon, invests the front of that bowel, and passes off on the other side of it to the lateral parietes: occasionally only does it dip beneath the descending colon so as to come in contact with itself and form a mesentery for it. A little lower down, however, namely, in the left iliac fossa, it always forms a mesentery for the sigmoid flexure of the colon, and, still lower down, for the first part of the rectum. The distinction, however, between iliac mesocolon and mesorectum, as the mesenteries of the sigmoid flexure and rectum are called, is quite arbitrary and unnatural; a continuous mesenteric duplicature, broad in the middle and tapering to each end, serves to give attachment to both the sigmoid flexure and the first part of the rectum. Proceeding from the root of the mesentery downwards in the middle line, the peritoneum covers the sacro-vertebral prominence, and, just below, it arrives at the rectum and forms a mesentery for its first portion as above stated. The peritoneum invests the front only of the second portion of the rectum, and at a variable distance from the anus quits it and extends across to the back of the bladder in the male, or vagina and uterus in the female, so that the lowermost portion of the rectum is destitute altogether of peritoneal investment.

From the other side of the root of the mesentery, namely, that which looks upwards and to the right, we may trace the continuity of peritoneal surface off to the right lumbar region, investing the ascending colon in a like, and similarly variable, manner to that in which it was described as investing the descending colon; and to the right iliac fossa, where it invests the cœcum, sometimes, but not most frequently, forming a narrow mesentery for it called the meso-cœcum. A bit of mesentery is usually afforded to the vermiform process, but this, of course, we do not reach by proceeding off laterally from the last-mentioned aspect of the root of the mesentery.

As mentioned above, the peritoneum extends across from the front of the rectum to the back of the bladder, in the male subject; the level at which it does so varies with the state of fullness or emptiness of the bladder, and also is said to vary, cæteris paribus, in different individuals; frequently it is so low that the peritoneum, passing across, touches the prostate. This is in the middle, between the front of the rectum and back of the bladder, but laterally the peritoneum is elevated into two antero-posterior folds, which extend across from the sides of the rectum to the sides of the bladder; these are called the recto-vesical folds or posterior ligaments of the bladder: anterior and external to them there are two other small folds. External to the recto-vesical folds the peritoneum does not descend nearly so low as it does between them; and therefore there is a remarkable, deepish, cul-de-sac, of the same breadth as the rectum, between that intestine and the bladder.

The posterior and lateral aspects and fundus of the bladder are invested with peritoneum, but not its anterior aspect: the peritoneum passes from the fundus of the bladder, by an even slant, on to the anterior abdominal parietes, not making any dip in front of it except when it is much distended. In the female there is a deep cul-de-sac of peritoneum between the rectum and uterus, descending low enough to be in contact with the vagina: between the uterus and bladder there is a second but much shallower cul-de-sac.

We have now traced the peritoneum over the ascending and descending portions of the colon to the abdominal parietes in the right and left lumbar region; from the recto-vesical folds and sides of the bladder to the iliac fossæ; and from the fundus of the bladder to the anterior abdominal parietes of the hypogastric region; from all or any of these positions, or from any point between them, we may trace the peritoneal free surface uninterruptedly up to our first starting point, the navel and falciform ligament of the liver. From the last-named position we have before reached the anterior and posterior surfaces of the lesser omentum, the former by tracing the free surface over the left lobe, and the latter by tracing it over the right lobe, of the liver. From the sides of the falciform hepatic ligament, proceeding in each lateral direction, in a horizontal sectional line taken at the level of the foramen of Winslow, to the left we find the free peritoneal surface continuing, uninterrupted by any folds, to the external surface of the gastro-splenic omentum in the left hypo-

Fig. 489.

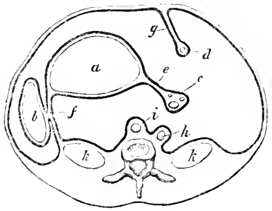

Diagram representing a transverse section of the human subject at the level of the first lumbar vertebra, i. e. through the foramen of Winslow.

a, the stomach, its descending portion; *b*, the spleen; *c*, the gall-duct and hepatic vessels; *d*, the round ligament of the liver; *e*, the lesser omentum; *f*, the gastro-splenic omentum; *g*, the falciform ligament of the liver; *h*, the vena cava; *i*, the aorta; *k*, *k*, the kidneys. The thick line represents the peritoneum. The space between the hepatic duct and vessels, *c*, and the vena cava, *h*, is the foramen of Winslow.

Fig. 490.

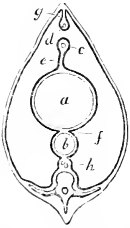

Diagram representing a transverse section of a Lizard, showing the stomach, spleen, lesser omentum, gastro-splenic omentum, and falciform hepatic ligament, in their mesial or typical position.

a, the stomach; *b*, the spleen; *c*, the gall-duct and hepatic vessels; *d*, the round ligament of the liver; *e*, the lesser omentum; *f*, the gastro-splenic omentum; *g*, the falciform ligament of the liver; *h*, the aorta, &c. The thick line represents the peritoneum. There is here no foramen of Winslow.

It will be seen by comparing these diagrams, that much of what seems so intricate in the human peritoneum results from a lateral displacement of an extremely simple arrangement, a displacement which attains its maximum in man, and is due, partly to the lungs being confined to the thorax, and partly to the great lateral, and small antero-posterior, measurement of the human figure.

chondriac region; to the right we find it continuing uninterrupted through the foramen of Winslow, covering its posterior boundary, to the internal surface of this same gastro-splenic omentum: to witness its continuity, however, up to the latter point, it is of course necessary to cut through the lesser omentum—in the human subject, but not in those animals which have no foramen of Winslow. (*Figs*. 489, 490.)

We have now examined the continuity of the peritoneum in all the main directions, and the mode in which it is maintained over the principal viscera and along the connecting sheets with two free surfaces. There yet remain for examination several folds and other remarkable arrangements of this membrane; the description of these is most conveniently deferred till we come to the consideration of our other propositions, when much that is at present wanting in order to render our proof of the continuity of the peritoneum throughout complete, will be supplied.

The peritoneal cavity is one cavity, in the same sense as the whole of the interior of an hour-glass is one cavity; that is to say, it is two large cavities made one by being connected by an extremely narrow communicating neck. Supposing the whole of the peritoneal sac could be detached from the connections of its external surface and expanded, it would be a sac of exceedingly irregular figure, divided into two parts by an extremely narrow constriction.

Omenta, mesenteries, and ligaments.—By these terms we understand the sheets with two free surfaces, formed by duplication of the peritoneum and adhesion of the surfaces thereby brought into apposition; to describe these is our second proposition, and to that we now pass.

A parieto-visceral sheet is usually called a *mesentery* or a *ligament;* a sheet with two free surfaces passing from one viscus to another is called an *omentum.*

The falciform ligament of the liver has already been fully described. We agree with Cruveilhier that its main use is to conduct the umbilical vein from the navel to the antero-posterior fissure of the liver. This, indeed, can hardly be called a use, especially in the adult; we would say rather that the existence of the falciform ligament necessarily results from the situation and course of the umbilical vein. It perhaps serves in some degree to retain the liver in situ, but it is not advantageously placed with regard to this office.

The coronary ligament of the liver is the name given to those portions of the peritoneum which leap across, so to speak, from the under surface of the diaphragm to the upper and posterior aspect of the liver. The anterior and posterior of these portions do not come in contact with one another in the middle, the liver being at that point in immediate contact with, and adherent to, the diaphragm; but towards each side the two layers gradually approach each other, and at length come in contact and adhere, and are prolonged as folds bearing another name. The coronary ligament fixes the liver to the diaphragm, or rather the deficiency of peritoneal investment to the diaphragm and liver between its anterior and posterior portions allows the liver to adhere to the diaphragm, and small vessels and lymphatics to pass from the one to the other.

The triangular ligaments of the liver are the continuations of the layers of the coronary ligament, become adherent as above, leaping across from the rounded posterior corners of the liver to the nearest or postero-lateral portion of the upper concave abdominal parietes, that is to say, to the diaphragm. Their form is, as their name indicates, triangular; their anterior borders are free; their posterior and internal borders are attached, the former to the parietes, the latter to the liver. They help to keep the liver in situ.

The lesser omentum has been partially described above. Between its layers are included the vena portæ, the hepatic artery, the gall-duct, and the hepatic plexus, along its free border; and the pyloric and coronaria ventriculi arteries, with accompanying veins and nerves, along its gastric attachment. Except in the course of these vessels, it is a thin transparent membranous sheet, with a very small amount of strength. The vessels destined for its own proper nutrition are extremely few and small. With regard to its use, Cruveilhier thinks that it is a true mesentery of the stomach, mesogastrium, but on this point we would offer the following remarks. One characteristic of a mesentery is, that it retains its bowel in situ, and this office the lesser omentum doubtless partially performs towards the stomach; but another characteristic of a mesentery is, that it gives passage to the arteries and veins of the bowel to which it belongs, and this office the lesser omentum performs, not for the stomach, but for the liver. It is the splenic omentum, or that part of the great omentum whereupon the spleen is sessile, extending between the parietal line of attachment running from the cardia to the left bend of the colon, and the fundus of the stomach, that conducts the principal gastric vessels, as the coronaria ventriculi, vasa brevia, and gastro-epiploica sinistra, from the parietes to the stomach. The splenic omentum fulfils indeed both these offices towards the stomach, and occupies with regard to it the position of a parieto-visceral fold, a relation still more characteristic of a mesentery.. We therefore are inclined to consider the splenic omentum as the mesogastrium; and some facts in comparative anatomy, (*figs.* 490, 491,) as well as that mentioned above, of its affording transit to the hepatic vessels, seem to indicate that the lesser omentum is the mesentery of the gall-duct and liver.

The splenic omentum is the name given to that long corner of the great omental pouch which extends up to the left of the fundus of the stomach as high as the cardia. It obtains its name from the circumstance of the spleen being situated on its outer aspect. The spleen, in a certain sense, is included between the layers; it is invested, however, by the outer layer alone,—the inner layer passes by it uninterruptedly. Soemmering mentions a *ligamentum phrenico-gastricum*, a peritoneal fold connecting the cardiac end of the stomach to the diaphragm; it is the very uppermost corner of this part of the great omental sac, which gets somewhat behind the cardia, and is not unfrequently complicated by one or two small falciform folds, rendered very conspicuous by pulling up the stomach. The attachments of this part of the great omental pouch have already been described; between its layers are contained, at its very tip or uppermost corner, the arteria coronaria ventriculi, with its accompanying vein and nerves;* and lower down the splenic vessels and nerves as far as from the parietes to the spleen, and the branches of the splenic vessels called vasa brevia and gastro-epiploica sinistra, as far as to the fundus of the stomach. There are a few lymphatic glands near the root of the spleen; such glands, together with fat in variable quantities, are very commonly included between the layers of the peritoneal duplicatures. The use of the splenic omentum is to retain the spleen and stomach in situ, and to give transit to the splenic and gastric vessels.

The great omentum, called also the gastro-colic omentum. The apron-like appearance and the sac-like form of this singular structure, and also its attachments, have been described above; it is necessary to add the following remarks. It extends much further down in the adult than in the fœtus. It reaches lower down on the left side than on the right. Owing to the proximity of its lower edge to the femoral and inguinal rings, it frequently constitutes a part or the whole of the contents of hernial sacs. It reaches lowest down when the stomach is empty, and is very considerably drawn up by distension of that organ. It is usually spread apron-like evenly over the small intestines, but is not unfrequently found lying folded up on one side or the other of the abdomen, occasionally even turned up over the liver and stomach. It is frequently loaded with immense quantities of fat, and indeed is seldom or never destitute of it along the sides of the vessels which form such a beautiful net-work between its layers. In the intervals or meshes of this network the omentum is so extremely thin that it is difficult to believe it composed of two layers, and not unfrequently the membrane is deficient in these situations, giving to the whole the appearance of a piece of lace finely perforated. This is always the condition of the great omentum of the dog, in which animal we have repeatedly assured our-

* The arteria coronaria ventriculi is rarely actually included between the layers of the splenic omentum in the human subject; the posterior aspect of the cardiac end of the stomach coming into immediate adhesion with the diaphragm, frequently allows of this artery reaching it without being enclosed in any peritoneal duplicature; not unfrequently, indeed, it is found to enter the corner of the gastro-hepatic omentum at once, and sometimes it occupies one of the little falciform folds just mentioned, but occasionally it is situated as the description indicates, and as this is its constant course in all or most of the inferior animals, we consider it and describe it as its normal one.

selves, by using great care in manipulation, that it is not the result of violence; it exists also in the mesenteries of some animals.

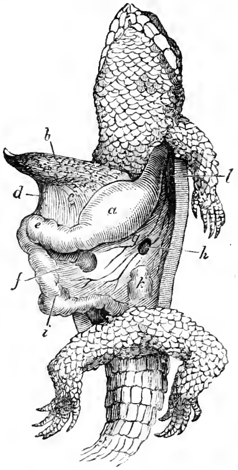
The arteries that ramify in the great omentum are branches of the gastro-epiploica dextra and sinistra, and some anastomosing ones from the colica media which pass round the colon and enter the omentum on the side of the intestine opposite to that on which the artery reaches it. Veins and doubtless nerves accompany these arteries, and there are some lymphatic glands enclosed between the layers of the great omentum along the greater curvature of the stomach.

The use of the great omentum has never been satisfactorily pointed out. It is peculiar to, and universal in, the class Mammalia, and therefore always co-exists with a diaphragm; probably it has some reference to the incessant motion and constantly recurring compression to which the intestines are subject from the action of that muscle in respiration. It is frequently seen dipping very deeply between the convolutions of the intestines, and occupying their interspaces as a moveable packing material, as if thereby enabling them to retain their cylindrical form whilst subject to incessant disturbance.

The great omentum, being continuous as one sheet with the splenic omentum, may be regarded as a great pouch or widening of the mesentery of the stomach. In those animals, such as the Carnivora, which have a very short colon, the great omentum does not extend from the stomach to the colon, but from the stomach to the pancreas, or to a transverse line of attachment corresponding in position with that of the transverse part of the duodenum in the human subject. The large intestine in these animals crosses over the small intestine at a point very near the termination of the latter in the cœcum, that is to say, over the lower part of the ileum, where it usually has a proper mesentery.*

The annexed drawing represents the abdominal viscera of a lizard. There is a preparation, showing the same parts of a lizard, in the Hunterian collection, (No. 444 D, Physiological Series.) The whole of the intestines of this animal, from the œsophagus to the rectum, are connected to the posterior abdominal parietes by one continuous mesentery attached along the mesial line. In the sheet situated anterior to the stomach, connecting that organ to the liver and enclosing the gall-duct in its free edge, we recognise the lesser omentum in what we heretofore considered its typical position. In that part of the mesentery which connects the upper part of the stomach to the posterior parietes we recognise the splenetic omentum; the spleen is seen enclosed between its layers—apparently a large mesenteric gland. That part of the common mesentery which, immediately succeeding the last mentioned, connects the middle and lower part of the stomach to the parietes, we cannot help regarding as the great omentum (the pancreas is just below this). Now pouch out this part towards the left, and a great omentum, such as is found in the Carnivora, is produced, with the same relation of other parts, except in the obliquity of the parietal attachment in the last-named animals, which is but slight. We have but to enclose the transverse colon between the layers of this sac, to obliterate that portion of the mesentery which is connected to the pancreas and duodenum, and to carry the transverse portion of the latter across just in the line of parietal attachment, in order to produce the condition of the parts which exists in man. It will readily be perceived how, in the mean time, a foramen of Winslow will have been formed by this imaginary manipulation.* We should deem this pouching or widening of the gastric mesentery to have reference to the great distention to which the stomach is liable, but that the sac is far too ample to be obliterated by any possible distention of that organ.

Fig. 491.



Abdominal viscera of a Lizard.

a, stomach; *b*, liver; *c*, lesser omentum; *d*, gall-duct; *e*, duodenum; *f*, pancreas; *g*, great omentum; *h*, spleen; *i*, cœcum; *k*, ovary and kidney; *l*, lung.

The transverse mesocolon, formed of two layers of peritoneum, derived as described above, is about six inches broad in the middle, and gradually narrows off on each side. It retains the transverse portion of the colon in situ, and transmits the veins, arteries, and nerves to this part of the intestine. At its root its two layers separate, leaving a prismoid space, which gives

* In some Carnivora, as the cat, the large intestine cannot be said fairly to pass over the small intestine at all.

* The whole duodenum of many mammalian animals, the cat for instance, has a mesentery; in that case the lower boundary of the foramen of Winslow is determined by the hepatic artery; in these animals this portion of the alimentary tube passes off downwards, so that no part of it is transverse.

passage to the transverse portion of the duodenum.

The mesentery is the peritoneal fold that connects the small intestine to the posterior abdominal parietes, giving transit to the vessels and nerves of that part of the intestinal tube. Numerous lymphatic glands, called mesenteric glands, are also included between its layers. It is eight inches in breadth at its widest part, and narrows off towards each end, where the small intestine becomes adherent to the parietes. Its parietal attachment, as mentioned above, is only a few inches in extent, whilst its visceral border is usually twenty feet long.

The ascending mesocolon, descending mesocolon, and *mesocæcum*, when they exist, and the *iliac* or *sigmoideal mesocolon* and *mesorectum*, which always exist, perform all the offices of mesenteries to those parts, respectively, of the intestinal tube which are indicated in their names.

The appendices epiploicæ are numerous small masses of fat, somewhat pyriform, and having a peritoneal investment, attached along the large intestine. Their use is not known; perhaps they serve as packing to the sacculated bowel on which they are placed.

The recto-vesical folds give transit to some vesical vessels and the umbilical arteries of the fœtus. The cellular tissue enclosed by them is very lax, so that they are easily unfolded by distention of the bladder.

The broad ligaments of the uterus are two folds of peritoneum passing from the lateral borders of the uterus to the opposite abdominal parietes. The line of their summits is about level with that of the superior border of the unimpregnated uterus. This summit or superior border of the broad ligament is defined by the Fallopian tube which it encloses; a little lower down on its posterior aspect the ovary is sessile upon it, invested in a secondary fold of its posterior layer: and the round ligament of the uterus passing between its layers from the side of the uterus to the inguinal canal carries out another little secondary fold in front of it. The broad ligament, then, and its secondary folds, enclose the ovary with its ligament, the Fallopian tube, the round ligament of the uterus, and the spermatic vessels and nerves. The layers of the broad ligament itself, but not those of its secondary folds, are connected together by loose areolar tissue, and are separated (the broad ligament itself becoming effaced) by the enlargement of the uterus in pregnancy.

There are a pair of *recto-uterine peritoneal folds* in the female and a pair of *vesico-uterine folds;* the former pass across from the sides of the rectum to the sides of the uterus, and represent the recto-vesical folds of the male; the latter pass across from the sides of the uterus to the sides of the bladder. The layers of both pairs are very loosely connected together.

There is a slight median fold and two slight lateral folds of the peritoneum lining the anterior abdominal parietes, converging from the fundus and sides of the bladder to the navel; they enclose the remains of the *urachus and of the two umbilical arteries of the fœtus.*

At the point corresponding with each internal abdominal ring in the male subject, there is a little infundibuliform depression or dimple of the peritoneal surface; it indicates the point from which a portion of peritoneum, being carried down with the testicle in its descent, was separated to form the tunica vaginalis—in the female; from the same points a cylindrical sheath of peritoneum accompanies the round ligament a little way into the inguinal canal; this sheath has been called the *canal of Nuck.*

With regard to our third proposition,—THE SEROUS COAT AFFORDED BY THE PERITONEUM TO THE VARIOUS VISCERA invests some of them completely, except along little linear spaces, imaginary rather than real, where it reaches them as mesentery, &c.: others it invests on one side only, and others again still more partially.

The liver has an investment of peritoneum complete, except at its posterior, thick, rounded border, over a space of inconstant form between the anterior and posterior layers of the coronary ligament, where the liver is in immediate contact with the diaphragm, the space corresponding with the gall-bladder, and along the little linear spaces where the falciform and triangular ligaments and the lesser omentum are attached to it.

The gall-bladder is invested with peritoneum on its lower aspect only; that side which is presented towards the liver is in immediate contact with it.

The stomach is completely invested with peritoneum, except at the two little linear spaces along its curvatures, where the lesser and greater omenta are attached to it.

The spleen is invested by the peritoneum completely, except at its hilus, where its vessels enter from the omentum.

The first or ascending portion of *the duodenum* has a complete peritoneal investment, except at a little linear space along its lower aspect, where the great omentum is attached to it, so that this portion is free to move. The second, or descending portion has peritoneal investment on its anterior aspect only. The third or transverse portion is invested with peritoneum along a very narrow portion of the upper, and a somewhat less narrow portion of the lower part of its anterior aspect; the whole of its posterior aspect and the middle part of its anterior are destitute of peritoneal covering, the former being adherent to the posterior abdominal parietes, &c., the latter corresponding with the root of the transverse mesocolon. Its upper aspect is adherent to the pancreas, which encroaches upon the upper one of the two spaces mentioned as invested with peritoneum. At the point where the duodenum is crossed by the colon, which is just where from descending it becomes transverse, the two bowels are in immediate contact, so that the duodenum is, at this point, destitute of peritoneal covering around its entire circumference. Where the superior mesenteric artery crosses the duodenum, the peritoneum is borne off from it by that vessel.

The pancreas is invested with peritoneum on its anterior surface only.

The peritoneum passes over the anterior surface of *the kidneys and suprarenal capsules*, but is not usually in immediate contact with them; a large quantity of loose areolar and adipose tissue being interposed.

The jejunum and ilium have a complete investment of peritoneum, except along the little linear space where the mesentery is attached to them.

The cæcum and the ascending and descending colon are always invested with a peritoneal coat in front, and this extends to a variable distance around their sides, sometimes completely covering them except at the little posterior linear spaces where their respective mesenteries, in such cases existing, are attached to them.

The transverse portion of the colon is completely covered by peritoneum except along two little linear spaces on the opposite sides of it, namely, on its anterior and posterior aspects, where the great omentum and transverse mesocolon respectively, as described above, are attached.

The sigmoid flexure of the colon and the first portion of the rectum are invested completely with peritoneum, except along the line of attachment of their respective mesenteries.

The second portion of the rectum has a peritoneal investment on its front only: its lateral and posterior aspects are destitute of such covering. The peritoneum, as above stated, passes across from the rectum to the bladder without descending low enough to afford any investment whatever to the lowermost or third portion of the rectum. The conventional division of the rectum into three portions is, in fact, founded upon this circumstance of its being first completely, then partially, and lastly not at all invested with peritoneum, as you proceed from above downwards. The summits of the recto-vesical folds landmark the point of junction of the upper and middle portions.

The whole of the posterior aspect, the fundus and the three upper fourths of the anterior aspect of *the uterus* are invested with a peritoneal coat. The os uteri, which projects into the vagina, the lower fourth of the anterior aspect, which is in immediate contact with the bladder, and the little lateral linear spaces where the broad ligaments are attached, are destitute of it.

The peritoneum reaches *the vagina* behind the uterus, and invests a small portion of it in that situation, but does not come into relation with it in front of the uterus.

The ovary is very closely and completely surrounded with peritoneum, which reaches it at its attachment to the broad ligament; we must in this case as heretofore describe a little linear space, at the point of attachment, as destitute of peritoneal vestiture.

The bladder is covered by peritoneum over a different extent in the two sexes. In both male and female its anterior aspect is destitute of peritoneal covering; and its fundus, in both sexes, has a peritoneal investment equally complete: with regard to the posterior aspect, however, in the male, the peritoneum covers it often as far down as the prostate, whilst it leaves uncovered a large portion of the lower part of this aspect of the bladder in the female.

The parietal portion of the peritoneum invests *the anterior and lateral abdominal walls* completely, except at the lower part, where it is borne off from the anterior walls by the bladder and along the linear attachment of the falciform ligament of the liver; *the under surface of the diaphragm*, except between the layers of the coronary ligament of the liver, and along the linear attachments to it of the falciform and triangular hepatic ligaments, the phrenico-gastric ligament, and the splenic omentum; *the posterior parietes*, except where the viscera, ducts, and vessels enumerated above as invested with the peritoneum on their front only, intervene. It does not, however, reach *the inferior abdominal parietes*, that is to say *the levator ani*, at any point, a quantity of loose cellular tissue occupying the interspaces of the pelvic viscera between that muscle and the lowest point to which the peritoneum extends.

We now come to the last of our propositions.

The external or adherent surface of the peritoneum is attached to the apposed tissues with different degrees of intimacy in different situations—a circumstance of great importance with regard to certain surgical operations. This attachment is intimate or otherwise, according as the areolar tissue that constitutes the connecting medium is abundant or scarce, loose or compact, in different situations. The connecting areolar tissue is continuous through the openings in the abdominal parietes with the other areolar sheets of the body. *The parietal portion* of the peritoneum is strengthened by a fibrous layer, so that abscesses seldom burst through it; whilst the visceral portion, being destitute of this layer, is not unfrequently burst through by abscesses of an abdominal viscus, as the liver. The peritoneum lining the under surface of the diaphragm is the most firmly attached of all the parietal portion. That which lines the anterior abdominal parietes is very intimately adherent along the linea alba and sheath of the rectus, but very loosely just above the pubis and about the internal abdominal ring. It is extremely loosely attached to the posterior abdominal parietes and immediately superjacent organs, and in the lumbar and pelvic regions and iliac fossæ—a very fortunate circumstance with regard to placing ligatures on the large abdominal and pelvic vessels without laying open the peritoneal cavity.

The visceral portion, as it covers the liver and spleen and the alimentary tube, is very intimately adherent to them except at the middle portion of the rectum. That which partially covers the bladder adheres very loosely to it; owing to which, together with the looseness of the peritoneal attachment above the pubis in front, to the rectum behind, and to itself in the recto-vesical folds, the bladder when distended rises high above the pubis between the abdominal parietes and peritoneum, pushing the latter up so as to diminish the depth of the recto-vesical cul-de-sac and leave its inferior fundus uncovered by it; consequently the bladder when distended may be punctured above the pubis or through the rectum without injuring the peritoneum.

In the mesenteries, omenta, and other peritoneal duplicatures, where the external surface of the peritoneum adheres to itself, the adhesion is generally extremely intimate. They are most separated where deposits of fat have taken place between them. The recto-vesical folds and the broad ligaments of the uterus alone, of all the peritoneal duplicatures, have their layers loosely adherent.

The peritoneum is very frequently the seat of extensive inflammation, the lymph effused in which process, besides causing adhesions of the abdominal viscera to one another and to the parietes, frequently covers the free peritoneal surface with a thick adherent layer or false membrane; and this, like some other tissues formed from lymph, shrinks or cicatrizes in every direction, and thereby produces some very curious secondary effects. In such cases, if the great omentum is free at its lower border, it becomes tucked up to the greater convexity of the stomach and apparently obliterated; or if adherent, as to a hernial sac, the shrinking of the new tissue that covers it drags down the stomach. The thin sharp edges of the liver become rounded by this agent, and the calibre of the intestinal tube diminished; sometimes the intestine is even strictured by the contraction of an unusually large deposit at a particular part. The tendency of this tissue to shrink, however, being controllable by sufficient mechanical resistance, is most manifest in those directions in which it experiences no such opposition; for which reason it tells more on the length than on the circumference of an intestine, and Cruveilhier met with a case of chronic peritonitis in which the small intestine measured only seven feet in length. If the hand is placed on the belly of a person in whom this condition exists, the muscles are felt to glide loosely over the peritoneum rendered tense beneath them.

For the minute anatomy of the peritoneum see Serous Membrane.

(Simon Rood Pittard.)

PHARYNX and Mouth. (Gr. φαρυγξ.)—The pharynx is a large, muscular, and membranous pouch, placed behind the nose, mouth, and larynx, and resting upon the cervical vertebræ: it extends from the base of the skull above to a level with the fourth or fifth cervical vertebra and the lower border of the cricoid cartilage, and is at this point continued into the œsophagus: it occupies the middle line of the body and is a symmetrical organ: of a very irregularly funnel-shaped form, it is wide above and open in front to the cavities of the nose and mouth, and contracts as it descends behind the larynx: by the relation of this latter organ the interior of the pharynx is converted into a tube to be continued downwards to the stomach under the name of œsophagus. A common channel to the digestive and respiratory passages, it is alike beautifully adapted by its construction, on the one hand to receive the food and convey it onward to the alimentary canal, and on the other to preserve a perfectly free communication between the atmospheric air and organs of respiration: to this latter function may be added the power of modulating vocal sounds.

As the pharynx is so closely associated, both in function and anatomical relation, with the mouth and palate, I shall subjoin to its description that of these latter organs. In the further examination of the pharynx the following arrangement will be adopted. 1st. The description of its aponeurosis and muscles. 2ndly. Its attachments considered generally. 3rdly. To examine its cavity with the several openings related to it. 4thly. The mucous membrane and glandular apparatus; and, lastly, the vessels and nerves distributed to it.

1. *The fibrous membrane.*—This aponeurosis, named cephalo-pharyngeal, contributes to the formation of the pharyngeal parietes above, and is essentially the means by which the pharynx is affixed to the base of the skull: it forms a sort of framework for the support of the muscular and mucous tunics above, and is imperceptibly lost as it descends between these structures: it is thin but strong and well-marked superiorly, and connected, by uniting intimately with the periosteum, to the under surface of the basilar process of the occipital bone, and, by a particularly dense slip, to its spine centrally; this latter may be considered as the origin of that tendinous raphé which, descending in the median line along the back of the pharynx, acts as an uniting medium to the constrictor muscles of either side: the basilar attachment of the cephalo-pharyngeal aponeurosis occurs immediately anterior to the insertions of the recti capitis antici muscles, and is consequently some little distance in advance of the occipital condyles and foramen: extending laterally, the aponeurosis next springs from the under surface of the petrous portion of the temporal bone as far outwardly as the external orifice of the carotid canal, just anterior and internal to which it turns suddenly forwards and inwards, forming a sharp angle, then passes beneath the inner surface of the levator palati muscle, to attach itself to the cartilaginous portion of the Eustachian tube, near the anterior extremity of which it terminates by being gradually lost upon the mucous membrane: descending from these several points, and bounding the upper part of the pharyngeal cavity posteriorly and laterally, it insinuates itself between the mucous membrane and superior constrictor muscle, and splitting up into filaments which pass between the numerous mucous glands that are found at this part of the pharynx is lost from an inch to two inches below the base of the skull: posteriorly, on either side the median line, and between the upper semicircular margins of the superior constrictor muscles and the base of the skull, a considerable part of this aponeurosis is uncovered by muscular fibres, constituting what are called the sinuses of Morgagni: the fibrous

membrane is of great width at its origin, the external carotid foramina marking off the lateral limits, but it quickly narrows as it descends: the sharp angle which it forms is brought into relation with the internal carotid artery and superior cervical ganglia of the sympathetic nerve: in the interior of the pharynx a longitudinal sulcus, sometimes crossed by a transverse slip, will be found behind the opening of the Eustachan tube, leading to a cul-de-sac which occupies this angle.

The pharynx is surrounded by muscular fibres which have been collected into three distinct muscles on either side, and named, from their action, constrictors; these may be considered as intrinsic: two other muscles on either side are inserted into its walls, and are extrinsic as not belonging so exclusively to it. The constrictor muscles are membraniform, spreading as thin muscular laminæ around the sides and back part of the pharynx, and have a common insertion into a posterior median raphé: they partly overlap each other from below upwards, so that the inferior constrictors alone can be wholly examined without interfering with the rest, and are invested on their outer surface with a dense fascia: they arise by numerous and distinct points of attachment, which gave occasion to their being divided originally into several muscles, each with its appropriate name given according to its particular origin: these are now reduced to three on each side, and arranged into superior, middle, and inferior.

*Constrictor pharyngis inferior.** — This muscle is the thickest and strongest of the set, has an irregular quadrilateral outline, and is situated at the lower part of the pharynx: it derives its origin from the cricoid and thyroid cartilages by two slips: the one, triangular and fleshy, arises from the side of the cricoid cartilage between the origins of the crico-arytenoideus posticus and crico-thyroideus muscles: from the latter it occasionally receives a few fibres: the other, broader and more extensive, lies on the ala of the thyroid cartilage, and arises from the two tubercles, which the ala presents on its external surface, and from a tendinous structure that stretches obliquely from one tubercle to the other: it is here blended with the attachments of the sterno-thyroid and thyro-hyoid muscles: it also embraces the inferior cornu of the thyroid cartilage: from these points it spreads round the side and back of the pharynx to the posterior median raphé, into which it is inserted conjointly with the muscle from the opposite side: the fibres pass in different directions: the superior are longer and pursue a more oblique course upwards, while the nearer they are examined to the lower margin of the muscle, the shorter and less oblique they become, and at length assume nearly a transverse direction. The origins of the inferior constrictor muscle are concealed by the thyroid gland and sterno-thyroid muscle: it is in relation laterally to the sheath of the carotid vessels, and posteriorly to the cervical vertebræ and deep muscles of the neck: its internal surface is applied partly upon the mucous membrane and the terminal fibres of the stylo-pharyngeus and palato-pharyngeus muscles, but to a greater extent upon the middle constrictor muscle: the oblique upper margin extends as high as the middle of the pharynx and close by its thyroid attachment allows the superior laryngeal nerve to pass beneath it: the circular fibres of the œsophagus are continued from its lower margin, but distinguished by their greater delicacy and paler colour: close to the cricoid cartilage the inferior or recurrent laryngeal nerve slips beneath its lower margin. Some of the lower fibres have occasionally been noticed to arise from the first ring of the trachea.

*Constrictor pharyngis medius** is of a triangular form, fixed by its apex to the hyoid bone and by an extensive base to the median raphé behind: its origin is received into the angle formed by the greater and smaller cornua of the os hyoides, to which processes the muscular fibres are attached as well as to the lower part of the stylo-hyoid ligament: the origin extends along the greater cornu quite to its posterior extremity, and is concealed by the hyo-glossus muscle, the lingual artery intervening: from this contracted commencement the middle constrictor spreads widely over the back of the pharynx, the superior fibres obliquely ascending towards the basilar process of the occipital bone, to the spine of which they are connected through the medium of the raphé, the muscle itself rarely reaching so high; the middle fibres take a more or less transverse direction, while the inferior descend under cover of the inferior constrictor: the whole muscle is inserted, with its fellow from the opposite side, into the raphé. After emerging from beneath the hyoglossus it is related to the external carotid artery and superior laryngeal nerve laterally, and to the vertebral column behind: by its internal surface it overlaps the superior constrictor, and is applied upon the stylo- and palato-pharyngei muscles and the mucous membrane. Near the great cornu of the hyoid bone the stylo-pharyngeus muscle insinuates itself beneath its upper border, separating it from the superior constrictor.

Constrictor pharyngis superior,† quadrilateral in shape and complicated from its very numerous attachments. The fibres of this muscle are paler and it is altogether thinner than the two former: it arises, firstly, by short tendinous fibres from the lower half of the posterior edge of the internal pterygoid plate and its hamular process; secondly, from an aponeurosis described as the inter- or pterygo-maxillary ligament common to it and the buccinator muscle, and which stretches from the inner pterygoid plate to the posterior extremity of the alveolar border of the inferior maxillary bone; thirdly, from the back part of the mylo-hyoid ridge;

* Thyro-pharyngeus, crico-pharyngeus.

* Hyo-pharyngeus.

† Cephalo-pharyngeus, pterygo-pharyngeus, mylo-pharyngeus, glosso-pharyngeus.

and, lastly, is said to arise from the side of the tongue near its base: this lingual origin is considered by some anatomists as a part of the genio-hyo-glossus muscle:* arising thus, the superior constrictor winds round the pharynx and is inserted into the cephalo-pharyngeal aponeurosis, upon which it is placed, and joins with its fellow from the opposite side at the median raphé. The superior fibres make a semicircular sweep upwards towards the spine of the basilar process, to which they are connected by the raphé: the rest pass more transversely to their insertion and are partially overlapped by the middle constrictor: between the upper border of this muscle and the base of the skull the pharyngeal aponeurosis is left uncovered by muscular fibres. The superior constrictor corresponds posteriorly to the cervical vertebræ, and is separated laterally from the internal pterygoid by a triangular space which is occupied by the internal carotid artery, internal jugular vein, and the eighth and ninth pairs of nerves: the stylo-pharyngeus muscle is also related to its outer side before it descends beneath the middle constrictor: by its internal surface it is applied upon the levator palati and palato-pharyngeus muscles, the mucous membrane and the tonsil.

The muscular layer thus formed round the pharynx is of varying thickness, the greatest strength prevailing behind the buccal cavity, where the inferior constrictor, in itself the strongest of these muscles, overlaps the middle: on the other hand, there is but little occasion for muscular action behind the nasal fossæ, so we find, in accordance with this circumstance, a greater delicacy in the fibres of the superior constrictor and a deficiency of muscle altogether higher up: probably, also, the overlapping of these muscles from below upwards and the oblique direction of many of their fibres have reference to the downward passage of the food. The margins of the constrictors, as these muscles lie on each other, are not very distinct, particularly towards the back part of the pharynx. Additional muscular slips have occasionally been observed by different anatomists, which may be briefly noticed:—1. fibres from the petrous process of the temporal bone to pass downwards and backwalds; 2. from the basilar process directed inwards; 3. from the internal pterygoid plate and hamular process directed downwards and inwards; 4. from the spinous process of the sphenoid and from the cartilaginous portion of the Eustachian tube.

Use.—Besides constricting the cavity of the pharynx, the inferior and middle constrictors can raise the larynx and carry it backwards, the latter through the medium of the os hyoides.

The extrinsic muscles of the pharynx are two on either side, the stylo- and palato-pharyngei.

Stylo-pharyngeus.—This is a long slender muscle, broader below than above, and arises from the inner side of the styloid process at its base, and from the neighbouring part of the vaginal process: it descends inwards and forwards towards the greater cornu of the os hyoides, and expanding insinuates itself beneath the upper edge of the middle constrictor muscle to be applied upon the mucous membrane of the pharynx: it is inserted with the palato-pharyngeus into the posterior border of the thyroid cartilage: soon after its origin it passes with the stylo-glossus muscle between the external and internal carotid arteries, lying upon the latter and the internal jugular vein: a particular feature in this muscle is its close relation to the glosso-pharyngeal nerve, which winds round its lower border from behind forwards: as it descends, its next relation is the side of the superior constrictor, and passing between it and the constrictor medius it is applied upon the mucous membrane of the pharynx.

Use.—The stylo-pharyngei raise and widen the pharynx, preparing it for the reception of the food: they are important muscles in deglutition: the larynx is also raised by them.

Palato-pharyngeus.—This muscle will be again referred to as belonging to the palate: its fibres are contained in the fold of mucous membrane known as the posterior pillar of the fauces: it expands upwards to the soft palate, and downwards to the pharynx under the superior constrictor: it descends to spread its fibres on the mucous membrane, and is inserted with the stylo-pharyngeus into the posterior border of the thyroid cartilage.

2. *General review of the attachments of the pharynx.*—By referring to the foregoing descriptive anatomy of its aponeurosis and muscles, the pharynx will be seen to form from one-half to two-thirds of a vertically elongated cylinder, open in front; and although before terminating, the interior of the pharynx is converted into a complete canal, it is so only by the relation of a totally distinct organ, viz. the larynx. Descending perpendicularly from the base of the skull to the lower border of the cricoid cartilage, the pharynx is applied evenly to the anterior aspect of the bodies of the cervical vertebræ and deep muscles of the neck, having a remarkably loose areolar tissue intervening, important as preserving to it a perfect freedom of motion, while, by its anterior edges, it is fixed to the internal pterygoid plates, to the pterygo-maxillary ligaments, by means of which it is continuous with the lateral walls of the mouth, to the inferior maxillary bone, the sides of the tongue and cornua of the os hyoides, thus forming behind the nasal and buccal cavities a large pouch, whose parietes being constantly strained apart by these attachments, preserve a perfectly free cavity, a circumstance of considerable importance with reference to the continual passage of air to and from the respiratory apparatus: continuing downwards, the pharynx next embraces the sides of the thyroid and cricoid cartilages, but as there is no longer occasion for this tension of its walls,

* Cruveilhier says "that those fibres of the genio-hyo-glossus, which occupy the interval between the os hyoides and the stylo-glossus, cover the corresponding portion of the pharynx, or rather the amygdaloid excavation." Valsalva and Santorini regard these fibres as forming a distinct muscle, and name it the glosso-pharyngeus.

they become flaccid, and are loosely applied to the posterior surface of the larynx, and so continued into the œsophagus: if examined from behind, the pharynx is seen to be of great breadth at the base of the skull, but narrows until opposed to the buccal cavity, where it again widens to contract somewhat abruptly at its termination: its lateral relations to the carotid vessels and nerves of the neck have been considered in the descriptions of the constrictor muscles.

3. *The cavity and its openings.*—The interior of the pharynx exhibits a cavity of considerable size, which is continuous with those of the nasal fossæ and mouth anteriorly and the canal of the œsophagus below. To study the varying dimensions of this cavity and the different openings which communicate with it, the pharynx must be slit up posteriorly and in the median line; its greatest breadth is behind the mouth, the buccal portion, which may be measured by the interval between the posterior extremities of the alveolar border of the lower jaw, and is rather more than two inches; thence narrowing upwards, the internal pterygoid plates will by their distance from each other, which is about one inch, give the diameter of the cavity at its nasal portion, while the distance between the posterior edges of the alæ of the thyroid cartilage will denote its breadth at the inferior or laryngeal portion: the antero-posterior diameter can vary but little, in consequence of the relation which the vertebral column has to the pharynx behind: during the act of deglutition these measurements are of course altered, but there is much less change of form in the upper or nasal portion of the cavity than in the rest of its extent. Dropping into the cavity from before backwards and from above downwards is the velum palati with the uvula depending from the centre of its posterior border: above this moveable curtain are seen the posterior openings of the nose with its median septum, the vomer: these are situated between the internal pterygoid plates, extend upwards to the base of the skull, and are limited below by the velum; they are quadrilateral in their outline and continued into the upper part of the pharyngeal cavity; a little way within the nasal fossæ and along their outer walls are seen the meatuses of the nose and the posterior edges of the inferior turbinated bones; prolonging these latter backwards by an imaginary line, we are brought to the openings of the Eustachian tubes; they are two narrow elliptical fissures, their long diameters, about three-eighths of an inch, directed from above downwards, and situated one on either side of the pharynx above the soft palate, and impinging the posterior edges of the internal pterygoid plates; they look forwards and inwards towards the inferior and middle meatuses of the nose, and are marked by prominent and rounded margins internally; an accurate knowledge of their relation to the nasal fossæ is of practical use in directing a probe or syringe into their canals; behind the openings of the Eustachian tubes are the longitudinal sulci which lead upwards and backwards to a cul-de-sac that occupies the angle formed by the sudden bending forward of the aponeurosis of the pharynx; below the velum is the posterior constricted aperture of the mouth, which will be again referred to in the description of the soft palate; it is limited above by the velum, below by the base of the tongue, and laterally by the posterior pillars of the fauces; the uvula depending from the velum centrally gives it a double arched outline above, but it is capable of assuming changes of form by the varied movements of its boundaries, which are especially concerned in deglutition; below the isthmus faucium and behind the base of the tongue is the superior aperture of the larynx, surmounted in front by the epiglottis; it is a triangular opening, the base directed forwards, and it has also an oblique direction from above downwards and from before backwards; it is generally completely closed during deglutition by the epiglottis being forced down upon it; on either side of the posterior surface of the larynx, between the thyroid and cricoid cartilages, are two gutters which lead downwards to the œsophageal opening of the pharynx; this opening has its long diameter from side to side in the flaccid state of its walls, but assumes a circular form when distended by the passage of food through it.

4. *Mucous membrane and glands.*—The interior of the pharynx is lined by a mucous membrane continuous with that investing the several cavities which open into it; it is of a reddish colour, and adherent to the muscular parietes by a thin submucous areolar tissue; from covering the back part and sides of the interior of the pharynx, it is to be traced along the under surface of the basilar process united to the periosteum through the medium of its submucous tunic, which at this part acquires considerable thickness, and is occasionally the seat of polypus; laterally and above it is reflected over the guttural orifice of the Eustachian tube, enters the canal, and is conducted by it to the cavity of the tympanum, forming an exceedingly thin lining to both; continuous with the mucous membrane, investing the upper surface of the velum, it passes through the posterior nasal openings into the nose; it may be next traced through the isthmus faucium, covering the under surface of the velum and posterior pillars of the fauces, to be continuous with the membrane of the buccal cavity, while more interiorly, after assisting to form the aryteno-epiglottidean folds of the laryngeal mucous membrane, it is reflected over the posterior surface of the larynx, to which it is connected so loosely by an areolar tissue as to be thrown into longitudinal folds, a provision for the dilatation of this part of the pharynx during the passage of the food; lastly, it is continued into the œsophagus. The mucous membrane above the velum palati, upon its upper surface and within the Eustachian tubes, is coated with epithelial prisms, corresponding in this respect with that which lines the greater part of the nasal cavities, while below the velum the epithelium assumes the lamelliform or scaly character. (See Mucous Membrane.) As it invests the upper

part of the pharynx its free surface presents numerous slight elevations occasioned by the glands which are situated beneath it; these indeed are scattered over the whole pharynx, but are especially abundant at its upper part, where they form a compact lamina between its musculo-membranous tunic and the mucous membrane, opening upon the surface of the latter by slender ducts.

5. *Vessels and nerves.*—The bloodvessels distributed to the pharynx are derived from several sources, but chiefly from an especial trunk, viz. the ascending or inferior pharyngeal artery; this vessel arises from the posterior part of the external carotid, often its first branch, near the bifurcation of the common carotid; it ascends to the base of the skull, lying close by the side of the pharynx and upon the rectus capitis anticus major muscle, sending off numerous small branches, which, intermingling with the pharyngeal plexus of nerves, are distributed to the constrictors and stylo-pharyngeus, to the velum, arches of the palate and tonsil, ending in minute ramifications on the mucous membrane; the next most regular supply is from the inferior palatine and tonsillitic branches of the facial artery; the internal maxillary, lingual and superior thyroid vessels contribute an irregular supply of small and unimportant twigs. The veins form a considerable plexus, the pharyngeal venous plexus, which is produced chiefly by the frequent anastomoses of the pharyngeal vein with the small branches that accompany the inferior palatine and tonsillitic arteries, and with some of the commencing twigs of the internal maxillary vein; the pharyngeal vein, which receives the blood from this plexus, opens, either singly or in conjunction with the lingual, into the internal jugular vein; of the lymphatics, but little is known; they probably enter the chain of glands which lie along the outer side of the carotid sheath. An intricate plexus of nerves, the pharyngeal plexus, is situated upon the sides of the pharynx, the branches being particularly numerous upon the middle constrictor muscle near its origin; it is of some length, and subject to variety in the number of its filaments in different subjects; it interlaces with the ramifications of the arterial twigs from the ascending pharyngeal, and derives its branches from the three portions of the eighth pair of nerves and from the superior cervical ganglion of the sympathetic; the glosso-pharyngeal nerve sends downwards two or more branches to the plexus; one of these I have seen to join the superior laryngeal nerve; they are given off just before the nerve winds round the lower border of the stylo-pharyngeus muscle; subsequently one or two branches penetrate this muscle to be distributed to the pharyngeal mucous membrane; the pneumo-gastric detaches one or two pharyngeal branches; the larger one appears in a great measure formed by a branch from the spinal accessory nerve; these join with the filaments from the glosso-pharyngeal; the superior laryngeal nerve by its external branch also contributes a few filaments; lastly, from the superior cervical ganglion of the sympathetic, twigs are derived, which, communicating with those already mentioned, complete this intricate plexus; the branches from it are distributed to the pharyngeal walls, to the soft palate, and stylo-pharyngeus muscles. The digastric branch of the facial nerve and the lingual or its descending branch are described as sometimes communicating with this plexus: for the more minute anatomy of these nerves see PAR VAGUM, GLOSSO-PHARYNGEAL NERVE, AND SPINAL ACCESSORY.

Mouth, (Gr. *στομα*; Lat. *os*; Fr. *bouche*.)—The mouth is an oval cavity, symmetrical, and situated at the lower part of the face, below the nasal fossæ, between the jaws, and in front of the pharynx, with which it communicates by a posterior opening, called the isthmus faucium, and has also a dilatable aperture anteriorly guarded by the lips: it is liable to considerable alterations of form and size, from complete closure to a state of extreme extension, when it represents a quadrangular pyramid with the base in front: the greatest change occurs in its vertical diameter from the movements of the lower jaw; in it are performed the various functions of mastication, tasting, partly that of deglutition, and it is subservient also to the production of articulate sounds. The mouth or buccal cavity is bounded both laterally and anteriorly by the alveolar borders of the upper and lower maxillary bones and teeth, the lips completing the boundary in front and the cheeks laterally: above it is roofed in by the arched palate and more posteriorly by the velum palati; inferiorly the tongue forms its floor. In the examination of these boundaries the reader is referred to the articles FACE and TEETH for the description of the maxillary bones and teeth.

The *lips* (labia) are two moveable curtains placed in front of the mouth, presenting between them when applied to each other a transverse slit convertible by their separation into a more or less considerable opening, which constitutes the anterior aperture of the buccal cavity: the lips are united at the lateral limits of this fissure to form the commissures or angles; the anterior surface of the upper lip, which usually projects a little beyond the lower, is covered with hair in the adult male, and exhibits in the median line a vertical groove continued to its free border from the septum of the nose: two ridges bound this furrow on either side, and from thence the upper lip passes off laterally to the cheek, insensibly in the young and plump face, but otherwise a line of demarcation is produced by an oblique fold of the skin which descends from the side of the nose to near the commissure of the lips on either side of the face: the anterior surface of the lower lip descends more or less abruptly backwards to the chin, divided from it by a transverse groove: it is covered with hair usually at the centre only, and slightly bulging near its free border shelves off gradually to the sides of the face: the free borders are the thickest parts of the lips, their large developement forming a characteristic feature in the Negro; in their outline they differ, presenting in the upper lip a projection in the centre, from which a curved line, gently arching upwards, proceeds laterally, while, in the lower, the centre exhibits a depression, and the line from it proceeds in a contrary direction, so that when the mouth is closed these borders are applied evenly to each other: they are of a red colour, turned outwardly, and marked from before backwards by slight wrinkles produced by the contraction of the orbicular muscle; their chief interest to the anatomist is in showing the continuity of the skin with the mucous membrane. Besides the tegumentary coverings of skin and mucous membrane, these organs contain within their thickness the orbicularis muscle, with which are blended the insertions of the greater number of the muscles of the face (see FACE), whose varied actions render these features so peculiarly expressive of the passions: numerous glands, vessels, and nerves, and an areolar tissue complete their structure. The labial glands constitute a thick lamina between the muscular and mucous layers, producing slight elevations upon the surface of the latter; they resemble the salivary glands in appearance, are of small but varying size, placed close to each other but perfectly distinct, each possessing a separate excretory duct, which opens upon the free surface of the mucous membrane. The lips are most abundantly supplied with vessels and nerves; the coronary arteries, from the facial, course along their free borders directly beneath the mucous membrane; they also receive numerous twigs from the buccal, infra-orbital, and mental branches of the internal maxillary and submental branch of the facial; the veins accompany the arterial branches; the lymphatics terminate in the glands at the base of the jaw, as evidenced by the frequent enlargement of the latter from the irritation of cancerous or other sores about the lips: the nerves are derived from the portio dura and fifth pair.

Use.—The lips are of great importance, more particularly the lower, in retaining the saliva within the cavity of the mouth, and are actively engaged in the acts of sucking and blowing; the utterance of many articulate sounds depends chiefly upon their action, and when viewed as organs of expression they are particularly adapted by their extreme mobility to indicate the passing thought.

The *cheeks* (buccæ) form the lateral extensible walls of the buccal cavity; examined from the interior of the mouth they will be found limited above and below by the reflexion of their investing mucous membrane upon the external surfaces of the superior and inferior maxillary bones: their superficial surface is bounded behind by the external ear and the posterior border of the lower jaw, below by the horizontal ramus of the same bone; superiorly they may be arbitrarily separated from the temple by the zygoma, and from the orbit by the lower margin of its cavity, and are continued anteriorly into the sides of the nose and lips; they therefore present somewhat of a quadrilateral outline, and in the young and healthy form a rounded projection outwards, but in the emaciated fall in towards the mouth. The skin of the cheek is smooth, thin, and delicate in front and above, and remarkable for its extreme vascularity, as seen in the act of blushing; it is covered behind and below in the adult male with hair, and in the aged its surface is more or less furrowed with wrinkles: the subcutaneous cellular tissue is dense and loaded with a variable quantity of fat, a particularly abundant mass of which is lodged between the buccinator and masseter muscles. The muscular structure of the cheeks has been already described in the article FACE. Between the muscles and mucous membrane are irregularly dispersed a considerable number of buccal glands; they are of small size, similar to those of the lips, and like them open upon the mucous surface by separate ducts: these openings are not likely to be mistaken for that of the parotid duct, which is marked by a very distinct prominence, is of larger size and situated opposite the interval between the second and third molar teeth in the upper jaw: there is an aggregation of several of these buccal glands, imbedded in the fat between the buccinator and masseter muscles, forming a larger glandular mass which opens into the mouth opposite the last molar tooth, and has been called the molar gland. The cheeks receive a rich supply of vessels from the facial, transverse facial, and internal maxillary arteries; the veins correspond to these branches and empty themselves into the internal and external jugular veins. The lymphatics probably terminate in the glands of the neck. As with other parts of the face, the cheeks derive their nervous filaments from the portio dura and fifth pair.

Use.—While the tongue guides the food outwardly to the teeth, the cheeks act in retaining it between them during mastication; they are employed during the act of sucking, and when distended by air or fluids they are actively engaged in forcibly expelling them, as exemplified in playing upon wind instruments or in squirting liquids from the mouth.

The palatine arch and gums.—The palatine arch or hard palate forms the greater part of the superior boundary of the buccal cavity: it has a parabolic figure, bounded laterally and in front by the teeth, and is continued posteriorly into the velum palati without exhibiting any line of demarcation: it presents mesially a whitish ridge, more prominent before than behind, which commences from a small eminence situated immediately behind the incisor teeth and corresponding with the lower orifice of the anterior palatine canal; the ridge then extends backwards and is traceable as far as the uvula; from it are passing laterally a variable number of transverse rugæ, apparent only at the anterior part of the palate, its buccal surface being, in the greater part of its extent, perfectly smooth. The palatine arch is framed by the palate processes of the superior maxillary and palate bones,* and invested on their

* See FACE.

under surface by a dense and thick mucous membrane: numerous glands with vessels and nerves also enter into its structure. The mucous membrane covering the bony palate with that forming the gums is of a paler colour than elsewhere in the interior of the mouth, and is united by a remarkably condensed and thick submucous areolar tissue to the periosteum, especially in the mesial line, where the two structures appear blended: on either side the union occurs by fibrous prolongations, allowing a thick layer of glands and the vessels and nerves of the palate to intervene: the membrane has a thick investment of epithelial scales, and is capable of resisting considerable pressure; of greater thickness before than behind, indifferently sensible, and in structure bears some analogy to that of the skin: the glands in every way resemble those of the cheeks and lips, and open in like manner upon the mucous surface; two larger openings than the rest may often be seen on either side the median line towards the back part of the palate.

The gums (Gr. ουλα, Lat. *gingivæ*) resemble in colour and structure the palatine membrane, except that the glandular apparatus is here reduced to mere follicular pores. They cover either surface of the alveolar processes of the jaws, intimately connected with the periosteum, and extend a little way beyond the alveoli to rest against the necks of the teeth by a festooned edge. The denticulated processes of this edge are continued across the alveoli between the teeth, by which means the gums on either surface communicate with each other; between these processes the concave margin of the gum is reflected upon itself to enter the alveoli, lining their inner surface, and closely applied to the fangs of the teeth. (See Teeth.) The palate and gums receive their arterial branches from the internal maxillary and facial arteries, and their nerves from the spheno-palatine or Meckel's ganglion. (See Fifth Pair of Nerves.) The palatine nerves gain the palate through the anterior and posterior palatine foramina, and course along immediately beneath the periosteum, lodged in grooves, together with the accompanying arteries, upon the inferior surface of the palatine processes of the superior maxillary and palate bone. The palatine arch constitutes the septum between the nasal and buccal cavities, and forms the fixed and resisting surface against which the tongue acts in deglutition and in the articulation of certain sounds; previous to the irruption of the teeth and after their decay, the gums are continued over the alveolar processes, and by their almost cartilaginous hardness supply their place; they are rendered peculiarly soft and spongy by the influence of mercury and scurvy upon the system.

The velum palati is a soft moveable curtain stretching backwards and downwards into the cavity of the pharynx from the posterior border of the hard palate, but so continuous with it as to exhibit no indication of their union. From its oblique direction the buccal or inferior surface is also anterior; it is concave, prolongs backwards the roof of the mouth, and presents the median ridge already noticed on the under surface of the hard palate. The nasal or superior surface looks upwards and backwards, is smooth, convex, and continuous with the floor of the nasal cavities; these surfaces terminate in a thin border posteriorly, which is prolonged downwards in the middle line to form the uvula. The uvula is of a conical shape, and varies in length and size in different individuals; it is occasionally found to be bifid at its extremity; it gives rise on either side near its base to two folds of mucous membrane, called the pillars of the fauces, which descend diverging towards the sides of the tongue at its back part, leaving between them an interval which is in a great measure occupied by the tonsil; the anterior pillar proceeds from the base of the uvula in front, and arching outwards and downwards terminates at the side of the tongue a little in advance of the V-shaped ridge of papillæ; the two anterior pillars together form what is denominated the anterior arch of the fauces. The posterior pillars constitute in fact the free border of the velum; they are nearer to each other at their commencement than the anterior, and from this circumstance (although on a plane posterior) can be seen at the same time with the anterior pillars on looking into the mouth; they spring from the sides of the uvula to take an arched course outwards and downwards and terminate in the sides of the pharynx. The posterior pillars laterally, with the velum and uvula above and the base of the tongue below, bound the constricted aperture between the cavities of the mouth and pharynx, which is called the isthmus faucium; the uvula dropping in the centre gives the superior outline of this opening a double arched form: it is extremely dilatable, and may be contracted nearly to complete closure by the muscular action of its walls; it is essentially concerned in the act of deglutition. The fossa which is left on either side between the anterior and posterior pillars is of a triangular shape, narrow above where the pillars approach each other, broader and deeper below as they diverge. The lower part of this will nearly correspond to the angle of the jaw.

Muscles of the velum palati.—These are on each side, the circumflexus or tensor palati and levator palati mollis, which descend from above to be attached to the velum near its upper surface; and the palato-glossus and palato-pharyngeus muscles, which descend from it to the tongue and palate; lastly there is the central azygos uvulæ muscle.

The circumflexus palati, tensor palati, or the peristaphylinus externus (pterygo-staphylin. Chauss.) is a flat, thin muscle, lying to the inner side of the internal pterygoid, and with it occupying the pterygoid fossa; it arises by tendinous and fleshy fibres from the scaphoid depression situated at the upper part of the inner pterygoid plate, and extending more outwardly, from a part of the external surface of the cartilaginous portion of the Eustachian tube. The muscle descends, partly tendinous and partly fleshy, resting against the outer surface of the internal pterygoid plate, but of sufficient breadth to extend beyond its posterior edge, and terminates in a tendon which winds round the hamular process; it is here retained in its situation by a small ligament and is surrounded by a synovial capsule to facilitate its movements. The tendon now alters its direction, for suddenly expanding into a thin but strong aponeurosis it spreads horizontally forwards and a little upwards to be inserted into the whole of the posterior border of the palatine process of the palate bone and into its posterior nasal spine, uniting with the tendon from the opposite side in the median line. It is in relation, so far as regards the vertical portion of the muscle, by its outer surface with the internal pterygoid, and by the inner with the internal pterygoid plate and the superior constrictor muscle of the pharynx. The horizontal tendons of these muscles form a firm aponeurotic expansion in the substance of the velum, which, when tightened by the contraction of the vertical muscular fibres, affords a powerful resisting surface to the upward pressure of the food while being thrust by the tongue through the isthmus.

The levator palati or peristaphylinus internus (petro-staphylin. Chauss.) is a flat and narrow muscle, and commences by a thin tendinous and fleshy origin which is attached to the under rough surface of the petrous portion of the temporal bone and neighbouring part of the cartilaginous portion of the Eustachian tube on its inner side; from thence it descends, resting upon the cephalo-pharyngeal aponeurosis, then slips beneath the upper edge of the superior constrictor muscle, and passes upon its internal surface to reach the palate; the muscle now takes a more horizontal direction inwards, and expanding spreads its fibres in the substance of the velum to unite with its fellow from the opposite side in the median line, and is also inserted into the posterior border of the expanded tendon of the circumflexus palati. The insertions of the levator and circumflexus palati muscles on either side form a thin stratum, tendinous in front and muscular behind, through the whole extent of the soft palate. The levator palati in its vertical course is related by its outer surface to the Eustachian tube and circumflexus palati muscle, from which latter it is soon separated by the superior constrictor of the pharynx; it is covered internally by the pharyngeal aponeurosis and mucous membrane: it is an elevator of the pendulous portion of the soft palate.

The palato-pharyngeus or pharyngo-staphylinus consists of a delicate bundle of fibres contained in the fold of mucous membrane, known as the posterior pillar of the fauces; it expands upwards into the substance of the velum and downwards into the pharyngeal walls. The muscular fibres which spread in the velum are very delicate and mingled with those of the palato-glossus: they are situated immediately beneath the levator palati muscle and reach across the palate to join with fibres from the muscle of the opposite side in the middle line: some of the fibres are attached also to the posterior edge of the circumflexus palati tendon: arching over the upper and posterior margin of the tonsil they contract to descend as a thin bundle in the posterior pillar of the fauces, and again expanding pass into the lateral wall of the pharynx between the mucous membrane and constrictor muscles; here they meet with the fibres of the stylo-pharyngeus muscle and have an attachment with them to the posterior border of the thyroid cartilage and to the pharyngeal mucous membrane. The principal action of these muscles is to contract the isthmus faucium, which they can do superiorly almost to obliteration; they can scarcely have much effect in raising the pharynx; if this latter be the fixed point, they may draw down the velum and so act as antagonists to the levatores palati.

The palato-glossus, or constrictor isthmus faucium (glosso-staphylinus), occupies the anterior pillar of the fauces and spreads its fibres in the velum with the palato-pharyngeus, then descends to expand upon the side of the tongue near its base, mingling its fibres with the stylo-glossus muscle. They may either act upon the velum by depressing it or raise the sides of the tongue to it.

Azygos uvulæ or palato-staphylinus is a slender fusiform muscle, or rather a pair of muscles lying side by side: a narrow slip of tendon attached to the posterior nasal spine gives origin to the muscular fibres, which proceed backwards and downwards in the middle line, resting upon the circumflexus and levator palati muscles, and are lost in the substance of the uvula, which organ they shorten.

The thickness of the soft palate is mainly dependent on a dense mass of small glands, a continuation in short of the series already described as occupying the structure of the palatine membrane. They form an extremely thick layer anteriorly, but as the velum thins to its posterior free border, so these glands become the more scattered as they are traced backwards; they lie between the muscles and the mucous membrane investing the under surface of the velum; a few also are scattered beneath the mucous membrane covering its upper surface, and a larger proportion of them in the substance of the uvula, its bulk being chiefly formed by them.

The tonsils or amygdalæ (αμυγδαλεα) are lodged in the interval between the pillars of the fauces: they are almond-shaped, with their larger extremities directed upwards, but vary in size in different individuals. They appear to consist of an assemblage of mucous glands, whose excretory ducts terminate in small sacs that are imbedded in the substance of the tonsil, and which open by larger or smaller orifices upon the surface of the mucous membrane. When the tonsils are inflamed these sacs exude a whitish secretion, which has some resemblance to an ulcer on their surface. The palato-glossus descends in front of and the palato-pharyngeus behind these organs; they are supported externally by the superior constrictor muscle, and are covered upon their internal surface by the mucous membrane of the mouth. In inflammatory enlargements of the tonsil it is closely related to the internal carotid artery, which vessel will be applied to its outer side and behind it, so that when an opening is required in the tonsil, the point of the lancet should be directed inwards towards the cavity of the mouth. The tonsils and soft palate are well supplied with blood by the palatine and tonsillitic branches from the facial, by the ascending pharyngeal and internal maxillary arteries. A considerable plexus of veins is formed round the tonsil, which terminates in the pharyngeal venous plexus. Besides the nervous twigs derived from the palatine branches of Meckel's ganglion, the soft palate also receives filaments from a plexus formed around the tonsils by the tonsillitic branches of the glosso-pharyngeal, which has been called the circulus tonsillaris. For the description of the tongue, the remaining boundary of the cavity of the mouth, see TONGUE.

Course of the mucous membrane.—The mucous membrane of the mouth is continuous with that of the pharynx and larynx. Commencing with the gums anteriorly, it passes upon the exterior surfaces of the upper and lower maxillary bones, and from thence is reflected on the cheeks laterally and upon the inner surface of the lips anteriorly, forming a small fold in the median line, called the frœnum, to each; it invests the free borders of the lips and becomes continuous with the skin at a well defined line of demarcation. When the jaws and teeth are closed, the cheeks and lips are naturally in apposition with them; but if separated by distending the cheeks, the mucous membrane we have been tracing will be seen to line an anterior or second buccal cavity forming a kind of antechamber to the interior of the mouth. Proceeding from the gums posteriorly the membrane descends upon the interior of the lower jaw to be reflected upwards to the under surface of the tongue, and forms for it anteriorly and in the median line a prominent fold, the frœnum linguæ; this occasionally is prolonged forwards to the apex of the tongue, interfering with its movements in the act of sucking: a slight division of the frœnum under these circumstances is all that is required. From the under surface of the tongue the mucous membrane invests that organ and is continued from its base to the epiglottis, and after forming three folds, called glosso-epiglottic, is reflected over its free edge to be continuous with the laryngeal membrane. From the gums of the upper jaw posteriorly it invests the hard and soft palate and passes round the posterior free border of the latter, after enclosing the uvula, to cover its nasal surface. From the cheeks laterally it is to be traced over the anterior pillars of the fauces, the internal surface of the tonsils dipping into its mucous crypts, and lastly forming the folds of the posterior pillars is continuous with the mucous membrane of the pharynx. Throughout the cavity of the mouth it is invested with epithelial scales, and its submucous areolar tissue is remarkably increased in thickness and density when forming the gums and palate.

Function.—The pharynx, mouth, and palate are most obviously associated in the process of deglutition, in which we may trace three successive stages: in the first, the food after being reduced to a softened pulp by mastication and admixture with the saliva is conveyed to the back part of the mouth by the movements of the tongue against the hard palate; this is a purely voluntary act and can be arrested at the will of the individual: the food carried past the anterior arch of the fauces, the second act of deglutition immediately succeeds; this involves the consentient action of numerous muscles and is a most complicated process. If the movements of the velum palati and the posterior pillars of the fauces are examined during an effort to swallow, the former is perceived to become somewhat more arched towards the cavity of the mouth and to be rendered tense, but it appears to maintain nearly its naturally oblique direction. It has been supposed that the velum is raised during deglutition, in order to prevent the food from passing to the nose, but this opinion is now generally considered erroneous. Müller says, "Most writers incorrectly state that during deglutition the food is prevented from entering the posterior nares by the soft palate being raised, a movement which, if performed, could not in any case completely cut off the pharynx from the posterior nares." With the stretching of the velum the posterior pillars or palato-pharyngei muscles will be seen to approach each other, particularly above, so as to reduce the isthmus faucium to a narrow triangular slit, broadest below. If the food is now pressed backwards by the tongue, it will be urged through this dilatable chink in a direction downwards and backwards, occasioned partly by the oblique resisting surface of the velum, and partly by the wider aperture left between the posterior pillars inferiorly, perhaps also by their greater disposition to yield in that direction to the pressure of the food as it passes between them; meanwhile the pharynx (and the larynx with it) has been drawn upwards, and at the same time widened by the action of the stylo-pharyngei muscles, to receive the morsel, which in passing into it presses the epiglottis down upon the superior aperture of the larynx, and gliding over it is then immediately carried on to the œsophagus by the action of the constrictor muscles. The epiglottis in being shut down upon the opening of the larynx protects the respiratory tube, but it is not absolutely essential for that purpose; experiments have been performed on animals where the epiglottis has been removed, and it has been destroyed by disease in the human subject without any material difference evidenced in deglutition, the action of the laryngeal muscles closing the aperture of the larynx. This second act of deglutition may be performed at will though only the saliva is swallowed, but the effort soon becomes fatiguing. When the food, however, has reached beyond a certain limit in the mouth, no effort on our part can prevent deglutition from taking place. (For the influence of the nerves upon this function and that of taste see Par Vagum, Spinal Accessory, Glosso-pharyngeal.) The further passage of the food through the œsophagus into the stomach (see Œsophagus) constitutes the third stage of deglutition and occurs involuntarily.

MORBID ANATOMY OF THE PHARYNX AND MOUTH.

Congenital malformations.—The pharynx in a very few instances only, presents any malformation; when such exists the pharynx terminates in a cul-de-sac. Sir A. Cooper has recorded a case of this kind, in which also the œsophagus was altogether wanting and the stomach without a cardiac orifice: the child lived eight days. In acephalous monsters a total deficiency of the pharynx has been noticed, but this is of very rare occurrence. The hard and soft palates are occasionally liable to congenital fissure: owing to an arrest of developement they fail to unite in the median line, and the result is what has been termed the cleft palate: this defect may be confined to the velum palati, or it may include the bony palate, and will sometimes extend through the front of the jaw: where the bony palate is involved the defect may vary from a mere fissure to an entire absence of the palatine arch, so that the nose and mouth are converted into a common cavity. The upper lip is not unfrequently fissured either on one or both sides of the median line, constituting the single or double hare-lip. This deformity may exist with or without the fissured palate, but cannot be considered as dependent simply on an arrest of developement; for at no period of fœtal life is the lip known to present this peculiar condition: the fissure may only partially divide the lip, or it may extend into the nose in an oblique or vertical direction. It is very rare to find the lower lip fissured.

Foreign bodies in the pharynx may produce immediate suffocation, either by mechanically obstructing the opening of the larynx or by inducing spasm of the glottis; when any difficulty occurs in the extraction of these bodies, it is more generally dependent on their form than size. Angular portions of bone, needles, &c. are likely to become fixed by the contraction of the pharyngeal walls upon their pointed edges.

Structural changes.—The mucous membrane of the pharynx and posterior part of the fauces is very frequently the seat of inflammation, either simple or of a specific character; thus, it rarely escapes in scarlatina and syphilis without exhibiting the effects of these poisons: the latter often producing, by ulceration and sloughing, total destruction of the soft or even of the hard palate and causing fearful mischief. The tonsils generally participate in these inflammatory affections, or they may become inflamed primarily. In quinsy, the swelling of the tonsil is excessively rapid, and the disease is prone to terminate in suppuration. One effect of frequent inflammatory attacks is an indolent enlargement of the tonsil, a condition which is often with difficulty remedied, and occasionally requires excision of that organ.

Abscess sometimes occurs in the reticular tissue between the pharynx and cervical vertebræ, and protrudes the posterior wall of the former forwards, so as to interfere with deglutition.

Ulceration of the pharynx occasionally happens; it may be the result of a simple or specific inflammation, and will sometimes proceed to the destruction of its walls: fistulous openings between it and the larynx or other neighbouring parts may be thus produced. Cancer of the pharynx is fortunately not common, but cases have been noticed in which it has occurred.

Polypi have sometimes been found to take their growth from the mucous membrane of the pharynx, and most commonly spring from that portion of it which covers the posterior aspect of the larynx. Dr. Monro mentions a case of this kind in which the polypus was of considerable length, hanging down in the œsophagus; another seat of origin in the pharynx is from the membrane as it invests the under surface of the basilar process of the occipital bone: they have been seen to grow also from the soft palate.

A pouch is occasionally formed either behind or on either side of the pharynx by an extrusion through the muscular coat of its mucous membrane. A preparation in the Museum at St. Thomas's Hospital exhibits such an arrangement: a blind pouch about three inches in length, and of course communicating with the interior of the pharynx, descends by the side of it: the muscular parietes do not appear to have been at all prolonged upon its surface.

The cheeks, gums, and lips in children are sometimes involved in a destructive ulceration, to which the term *cancrum oris* has been applied; it may extend to almost any length, destroying the cheek, the lips, the gums, and teeth: it is seldom seen in adults. The gums, besides the softened and spongy change induced by scurvy and the well known effect caused by the introduction of mercury into the system, are also affected with the disease called epulis. In this case the gum is enlarged, reddened, and ulcerates, and demands excision of the entire diseased structure: it is generally considered of a malignant nature. The lower lip is sometimes the seat of cancerous ulceration; it has been questioned whether this disease is really true cancer. Sir A. Cooper, however, says, in his lectures, "That the disease is of a scirrhous nature, even at the beginning, any surgeon must be satisfied; it is hard, has a bleeding surface, everted edges, and, as it proceeds in its destructive course, communicates disease to the glands: there is likewise felt in it, at particular periods, the most dreadful pain. An operation for the complete removal of the disease is the patient's only real hope of succour." It is very rare for the same disease to originate in the upper lip.

(*William Trew.*)

PISCES. (Eng. *Fishes;* Fr. *Poissons*; Germ. *Fische.*)—The lowest class of the vertebrate division of the animal kingdom, embracing numerous oviparous races of beings fitted by their organization to live only in water, and consequently they are the appropriate inhabitants of the ocean and of inland streams and lakes. Being strictly aquatic in their habits, Fishes respire through the medium of the element in which they live by means of gills or branchiæ, that are connected with a framework of bony or cartilaginous arches situated on the sides of the neck, to which the water obtains free access, generally passing in at the mouth and escaping through lateral openings situated behind the head. Their heart is bilocular, and consists of an auricle and ventricle, which, receiving the venous blood from the system, propel it over the respiratory surface, whence it is collected into an arterial trunk, the aorta, by which it is distributed over the body without the intervention of a systemic heart. Their blood is of very low temperature, and their bodies are generally covered with scales of various kinds, whereby they are preserved from maceration in the surrounding water, and fitted to glide smoothly through the fluid medium wherein they live. Their principal instrument of progression is their tail, which is generally expanded into a broad fin, that strikes the water by alternate lateral movements. Besides this *caudal* fin others are frequently met with situated along the median line of the body, to which the names of *dorsal* and *anal* fins have been appropriated accordingly as they are situated upon the back or behind the anal outlet of the body. The position of these azygos fins is vertical, and their use to a fish is similar to that of the keel or of the helm to a ship. The representatives of the anterior and posterior extremities of other Vertebrata likewise take the form of fins, and are only fitted for progression in the water: these are generally four in number, namely, the two *pectoral fins*, which represent the anterior extremities; and the two *ventral fins*, corresponding with the posterior limbs of Quadrupeds. Great variety is met with both in the number and position of these locomotive members; generally all four are present; frequently one pair is deficient, and sometimes they are altogether wanting. In situation they likewise vary, more especially the ventral pair, which in some races, instead of being behind, are situated in front of the abdomen, in connection with the scapular apparatus, and even anterior to the pectoral fins.

In the construction of their cerebral system Fishes evidently stand lowest in the vertebrate scale, and every part of their economy indicates their inferiority to Reptiles, Birds, and Mammals.

The general attributes of Fishes and their relative position in the animal scale are so well laid down by their great modern historian, Cuvier, that it would be presumptuous not to give his own words.

" Breathing by the medium of water, that is to say, only profiting by the small quantity of oxygen contained in the air mixed with the water, their blood remains cold; their vitality, the energy of their senses and movements are less than in Mammalia and Birds. Thus their brain, although similar in composition, is proportionally much smaller, and their external organs of sense not calculated to impress upon it powerful sensations."*

" Fishes are in fact, of all the Vertebrata, those which give the least apparent evidence of sensibility. Having no elastic air at their disposal, they are dumb, or nearly so, and all the sentiments which voice awakens or entertains they are strangers to. Their eyes are as it were motionless, their face bony and fixed, their limbs incapable of flexion and moving as one piece, leaving no play to their physiognomy, no expression to their feelings. Their ear, enclosed entirely in the cranium, without external concha, or internal cochlea, composed only of some sacs and membranous canals, can hardly suffice to distinguish the most striking sounds, and, moreover, they have little use for the sense of hearing, condemned to live in the empire of silence, where every thing around is mute."

" Even their sight in the depths which they frequent could have little exercise, if most of them had not, in the size of their eyes, a means of compensation for the feebleness of the light; but even in these the eye hardly changes its direction, still less by altering its dimensions can it accommodate itself to the distances of objects. The iris never dilates or contracts, and the pupil remains the same in all intensities of illumination. No tear ever waters the eye—no eyelid wipes or protects it—it is in the Fish but a feeble representative of this organ, so beautiful, so lively, and so animated in the higher classes of animals."

" Being only able to support itself by pursuing a prey which itself swims more or less rapidly, having no means of seizing it but by swallowing, a delicate perception of savours would have been useless, if nature had bestowed it; but their tongue almost motionless, often entirely bony or coated with dental plates, and only furnished with slender nerves, and these few in number, shews us that this organ also is as obtuse as its little use would lead us to imagine it."

" Their smell even cannot be exercised so continually as in animals which respire air and have their nostrils constantly traversed by odorous vapours."

" Lastly, their touch, almost annihilated at the surface of their body by the scales which clothe them, and in their limbs by the want of flexibility in their rays, and the nature of the membranes investing them, is confined to the ends of their lips, and even these in some are osseous and insensible."

" Thus the external senses of Fishes give them few lively and distinct impressions. Surrounding nature cannot affect them but in a confused manner; their pleasures are little varied, and they have no painful impressions from without but such as are produced by wounds."

" Their continual need, which, except in the

* Cuvier and Valenciennes, Histoire des Poissons.

breeding season, alone occupies and guides them, is to assuage the internal feeling of hunger, to devour almost all that they can. To pursue a prey or to escape from a pursuer makes the occupation of their life; it is this which determines their choice of the different situations which they inhabit; it is the principal cause of the variety of their forms and of the special instincts or artifices which nature has granted to some of the species."

"Vicissitudes of temperature affect them little, not only because these are less in the element which they inhabit than in our atmosphere, but because their bodies taking the surrounding temperature the contrast of external cold and internal heat scarcely exists in their case. Thus the seasons are not so exclusively the regulators of their migration and propagation as amongst Quadrupeds or more especially Birds. Many Fishes spawn in winter; it is towards autumn that herrings come out of the north to shed upon our coast their spawn and milt. It is in the north that the most astonishing fecundity is witnessed, if not in variety of species, at least in individuals; and in no other seas do we find anything approaching to the countless myriads of herrings and cod which attract whole fleets to the northern fisheries."

"The loves of Fishes are cold as themselves; they only indicate individual need. Scarcely is it permitted to a few species that the two sexes should pair and enjoy pleasure together; in the rest the males pursue the eggs rather than seek the females; they are reduced to impregnate eggs the mother of which is unknown, and whose produce they will never see. The pleasures of maternity are equally unknown to most species; a small number only carry their eggs with them for a short time; with few exceptions Fishes have no nest to build and no young to nourish: in a word, even to the last details, their economy contrasts diametrically with that of Birds."

In no class of the animal kingdom do we find such diversity of form as in that of Fishes. Some amongst them are perfectly spherical, as the *Diodons*. Others are discoidal, or flat and circular, and this shape may be produced by two very different conditions, resulting either from an excessive narrowing or inordinate expansion of the two sides of the body. In the first case it is compressed and much elevated, as in Vomer and Orthagoriscus, while in the second case it is much depressed, flattened, and very broad, as in the Skates. Other species are oval, more or less elongated and slightly compressed laterally, such as Carp, Trout, &c., which is the most ordinary shape. Nevertheless when these become extended longitudinally (as in the Pikes for example), we are insensibly conducted by all intermediate gradations of form to the cylindrical Eels, or to compressed and riband-shaped Fishes, such as Cepola. Perhaps the most remarkably shaped Fishes are those whose bodies are bounded by nearly flat surfaces, and which circumscribe angular figures, such as triangles, squares, pentagons, hexagons, &c., (*Ostracion, Syngnathus.*) There are even certain genera in which the two sides are not symmetrical, one being flattened and the other vaulted, and in these races even the bones of the cranium are so disproportioned that both eyes are turned to the same side of the animal (*Pleuronectidæ*).

The following arrangement, being a modification of the classification proposed by Cuvier, will facilitate our investigations relative to the anatomy of the numerous members of this extensive class.

PISCES.

Division I.— *CHONDROPTERYGII.*

Skeleton cartilaginous, fins supported by cartilaginous rays.

Order I.—Branchiæ fixed.

1*st Family.* — Plagiostomata. *Squalus, Zygæna, Squatina, Pristis, Raia.*

Order II.—Branchiæ free.

1*st Family.* — Sturionidæ. *Accipenser, Spatularia, Chimæra.*

Division II.—*OSTEOPTERYGII.*

Skeleton composed of true bone.

Order I.—ACANTHOPTERYGII.

The Fishes belonging to this division are at once recognised by the stiff spines which constitute the first fin-rays of the dorsal fin, or which support the anterior fin of the back in case there are two dorsals. In some cases the anterior dorsal fin is only represented by detached spines. The first rays of the anal fin are likewise spinous as well as the first ray of the ventral fin. This order, which comprises by far the greater number of osseous Fishes, is divisible into the following families.

1*st Family.* — Percidæ. *Perca, Labrax, Lates, Centropomus, Grammistes, Aspro, Apogon, Cheilodipterus, Pomatomus, Ambassis, Lucio-Perca, Serranus, Plectropoma, Diacope, Mesoprion, Accrina, Rypticus, Polyprion, Centropristis, Gristes, Cirrhites, Chironemus, Pomotis, Centrarchus, Priacanthus, Dules, Therapon, Pelates, Helotes, Trichodon, Sillago, Holocentrum, Myripristis, Beryx, Trachichtys, Trachinus, Percis, Pinguipes, Percophis, Uranoscopus, Polynemus, Sphyræna, Paralepis, Mullus.*

2*nd Family.*—Sclerogenidæ (hard cheeks). *Trigla, Prionotes, Peristedion, Dactylopterus, Cephalacanthes, Cottus, Hemitripterus, Hemilepidotus, Platycephalus, Scorpæna, Pterois, Blepsias, Apistes, Agriopes, Pelors, Synanceia, Monocentris, Gasterosteus, Oreosoma.*

3*d Family.* — Sciænidæ. *Sciæna, Eques, Hæmulon, Pristipoma, Diagramma, Lobotes, Cheilodactyles, Scolopsides, Micropterus, Amphiprion, Premnas, Pomacentres, Dascyllus, Glyphisodon, Heliases.*

4*th Family.*—Sparidæ. *Sargus, Chrysophris, Pagrus, Pagellus, Dentex, Cantharus, Boops, Oblada.*

5*th Family.*—Mænidæ. *Mæna, Smaris, Cæsio, Gerrus.*

6*th Family.* — Squammipennes. *Chæto-*

don, *Psettus*, *Pimelepterus*, *Dipterodon*, *Brama*, *Pempheris*, *Foxotes*.

7th Family. — SCOMBERIDÆ. *Scomber*, *Xiphias*, *Centronotus*, *Rhincobdella*, *Campilodon*, *Seriola*, *Nomeus*, *Temnodon*, *Caranx*, *Vomer*, *Zeus*, *Stromateus*, *Sesarinus*, *Kurtus*, *Coryphæna*.

8th Family.—TÆNIOIDES. *Lepidopus*, *Trichiurus*, *Gymnetrus*, *Stylephorus*, *Cepola*, *Lophotes*.

9th Family.—THEUTIDÆ. *Siganus*, *Acanthurus*, *Prionurus*, *Naseus*, *Axinurus*, *Priodon*.

10th Family. — WITH LABYRINTHIFORM PHARYNGEAL BONES. *Anabas*, *Polyacanthus*, *Macropodes*, *Helostomus*, *Asphromenus*, *Trichopodes*, *Spirobranchus*, *Ophicephalus*.

11th Family.—MUGILIDÆ. *Mugil*, *Tetragonurus*, *Atherina*.

12th Family.—GOBIDÆ. *Blennius*, *Anarrhicas*, *Gobius*, *Callionymus*, *Platypterus*, *Labrax*.

13th Family.—WITH PECTORAL FINS FEET-LIKE. *Lophius*, *Batrachus*.

14th Family.—LABRIDÆ. *Labrus*, *Xirechthys*, *Chromis*, *Scarus*.

15th Family. — WITH FLUTE-SHAPED MOUTHS. *Fistularia*, *Centriscus*.

All the other osseous Fishes have the rays that support the fins soft and composed of numerous pieces articulated with each other, with the exception, in some cases, of the first ray of the dorsal or of the pectoral. These are divided in accordance with the situation of the ventral fins, which are sometimes placed beneath the abdomen, sometimes appended to the framework of the shoulder, or, lastly, are altogether wanting. Three distinct orders are thus established, viz., MALACOPTERYGII ABDOMINALES, MALACOPTERYGII SUBRACHIALES, and MALACOPTERYGII APODES.

ORDER II.—MALACOPTERYGII ABDOMINALES. Having their ventral fins suspended beneath the abdomen and behind the pectorals, without any connection with the bones of the shoulder. This order comprehends most fresh-water Fishes.

16th Family.—CYPRINIDÆ. *Cyprinus*, *Cobitis*, *Anableps*, *Pæcilia*, *Lebias*, *Fundulus*, *Molinesia*, *Cyprinodon*.

17th Family.—ESOCIDÆ. *Esox*, *Exocetus*, *Mormyrus*.

18th Family.—SILURIDÆ. *Silurus*, *Malapterurus*, *Aspredo*, *Loricaria*.

19th Family.—SALMONIDÆ. *Salmo*, *Sternoptyx*.

20th Family.—CLUPEIDÆ. *Clupea*, *Odontognathus*, *Pristigaster*, *Notopterus*, *Engraulis*, *Megalops*, *Elops*, *Butirinus*, *Chirocentrus*, *Hyodon*, *Erythrinus*, *Amia*, *Sudis*, *Osteoglossum*, *Lepisosteus*, *Polypterus*.

ORDER III.—MALACOPTERYGII SUBRACHIALES. This order is distinguished by the ventral fins being situated beneath the pectoral, the pelvis being suspended immediately from the framework of the shoulder.

21st Family.—GADIDÆ. *Gadus*, *Lepidoleprus*.

22nd Family.—PLEURONECTES. *Platessa*, *Hippoglossus*, *Rhombus*, *Solea*, *Monochirus*, *Achirus*.

23rd Family.—DISCOBOLI. *Lepadogaster*, *Cyclopterus*, *Echeneis*.

ORDER IV. — MALACOPTERYGII APODES. Ventral fins totally wanting.

24th Family.—ANGUILLIFORMES. *Muræna*, *Saccopharynx*, *Gymnotus*, *Gymnarchus*, *Leptocephalus*, *Ophidium*, *Ammodytes*.

ORDER V.—LOPHOBRANCHII. In all the preceding orders the gills are pectinated, but in the Lophobranchii the respiratory organs consist of little round tufts, disposed in pairs along the branchial arches.

25th Family.—SYNGNATHIDÆ. *Syngnathus*, *Pegasus*.

ORDER VI.—PLECTOGNATHI. This order of Fishes is distinguished by having the superior maxillary bones consolidated with or firmly united to the intermaxillaries, which latter form the margin of the jaw. The opercula and branchiostegous rays are, moreover, so concealed by the thick skin that nothing is visible externally but a small branchial fissure.

26th Family. — GYMNODONTES. *Diodon*, *Tetraodon*, *Orthagoriscus*, *Triodon*.

27th Family. — SCLERODERMES. *Balistes*, *Ostracion*.

DIVISION III.—*DERMAPTERYGII.*

Skeleton cartilaginous or membranous; fins without either cartilaginous or bony rays, or possessing the merest rudiments of them.

ORDER I.—CYCLOSTOMATA.

28th Family.—Petromyzon, *Myxine*.

ORDER II.—BRANCHIOSTOMATA.

29th Family.—Branchiostoma.

As regards the texture of their bones, Fishes may be divided into osseous, fibro-cartilaginous, and true cartilaginous.

The cartilaginous, otherwise called Chondropterygii, and which by their entire skeleton, by their branchiæ, the external border of which is fixed to the skin, and from which the water escapes through narrow and multiplied orifices, as well as by other details in their economy, are distinguished from other Fishes, have never true bones; their skeleton consists internally of a semi-transparent cartilage, which in Rays and Sharks is coated at its surface only with a layer of opaque and calcareous grains.

The Sturgeon and Chimæra have the bones of the spine as soft as those of the Chondropterygii, but the first of these genera has in many of the bones of the head and shoulder, at least a layer at the surface, completely ossified.

Other Fishes differ widely from each other in the hardness of the parts of their skeleton, and the fibro-cartilaginous have from this circumstance been erroneously associated with the Chondropterygii. In these, however, the calcareous matter, that is to say, the phosphate of lime, is deposited by fibres and layers in the cartilage, which serves as a basis to their bones, as is the case with the most perfectly osseous

Fishes. It is only less abundant, and consequently the texture of the bone does not become so hard or homogeneous.

It is very gratuitously that the skeleton of ordinary Fishes has been supposed to be more flexible, of a softer nature, and more extensible than in the superior classes of Vertebrata. Most Fishes have their bones as hard as or harder than other animals, and there are even some, in the texture of which neither pores nor fibres are distinguishable, and which appear homogeneous or even vitreous to the eye.

No Fish, either osseous or cartilaginous, has a medullary canal in its bones; but there are some, as the Trouts, in which the bony tissue is more or less penetrated with an oily fluid.

There are some Fishes in which, whilst the rest of the skeleton acquires great hardness, some parts remain always cartilaginous, as for example, the head of the Pike.

Skeleton of osseous Fishes.—In osseous Fishes, we shall regard the skeleton as being composed of the head, of the respiratory apparatus, of the trunk, comprising the body and tail, and of the limbs, viz, the pectoral and ventral fins. The vertical fins, viz, those of the back, anus, and tail, may be regarded as forming part of the trunk.

The *head* having more moveable appendages than that of Quadrupeds must be divided into a greater number of regions. We may distinguish in it the cranium, the jaws, the bones placed under the cranium behind the jaws, serving for their suspension and motions; the opercular bones, forming flappers, which open and shut the openings of the branchiæ; the bones surrounding the nostril, which are nearly external, as also are those around the eye or the temple, or which cover a part of the cheek.

The *respiratory apparatus* comprises the os hyoides and its appendages, that is to say, the branchiostegous rays and the arches supporting the branchiæ, as also the different pieces attached to these arches, and which altogether perform the functions of larynx and of trachea; lastly, the bones placed at the entrance to the pharynx, forming in some measure a second pair of jaws.

The *trunk* is composed of the vertebræ of the back and tail (for we can hardly say there is a neck, neither is there any sacrum,) of the ribs, of the bones called interspinous, which support the dorsal and anal fins; also the rays of these fins, as well as of the tail. These rays, whether they have branches or articulations, or are simply spinous, are always divisible into two lateral halves. There is rarely a sternum, properly so called, in Fishes; and when it exists, it is formed of pieces which are almost external, and which unite the lower extremities of the ribs.

The *anterior extremity* or pectoral fin comprehends the shoulder, which is an osseous semicircle composed of many bones, suspended at the upper part to the cranium or spine, and uniting inferiorly with its fellow of the opposite side. We may here find bones analogous to the two pieces of the scapula of Reptiles, to the humerus and to the bones of the forearm; there is even generally a process composed of two pieces protruding backwards, in which we might seek to see the coracoid bones and even the clavicle.

The two bones comparable to the radius and ulna carry at their edge a row of ossicula, which appear to represent those of the carpus, and which support the rays of the pectoral fin, with the exception of the first, which articulates at once with the radial bone.

The *posterior extremity* is much more variable in position than among Mammalia; its external or moveable portion, called *the ventral fin*, emerges sometimes before, sometimes behind, and sometimes immediately beneath the anterior extremity. The pelvis is composed of four bones, the largest and most constant of which, being always in front of the anus and genital orifices, may be considered as a sort of pubis, and these carry on a part of their posterior edge the rays of the ventral fin, without intermediate bones which can correspond either to femur, tibia, fibula, or tarsus. The rays of the pectoral and ventral fins, as of those of the single ones, are divisible longitudinally into two portions.

Vertebral column.—The vertebræ of a Fish are at once recognisable by the deep conical cavities which form the articulating surfaces whereby they are connected together, so that a double hollow cone always occupies the interval between two vertebræ, which in the living state is filled up by a soft membranous and gelatinous substance, which passes from one intervertebral cavity into another through holes which generally perforate the centres of the bodies of the vertebræ.

In Fishes, as in all other animals, each vertebra presents superiorly a ring for the passage of the spinal medulla bounded by the superior spinal laminæ *(neurapophyses)*, which is generally surmounted by a long spinous process, *(fig.* 493, 4,) at the base of which are situated both upon the anterior and posterior aspect little eminences that correspond to the articulating processes of other Vertebrata; but most generally these processes only touch or slightly overlap those of the neighbouring vertebræ without their being connected together by articulating facets. Sometimes, indeed, they exist on one side of the vertebra and not on the other, so that they have no correspondents wherewith to articulate. The annular part of the first vertebra is frequently separated from the body during the whole lifetime of the Fish, but in the other vertebræ no such separation is visible.

In some families, as in the *Murænidæ*, part of the anterior vertebræ have a little crest or vertical apophysis developed from beneath the body. Other races have a portion of the bodies of their vertebræ soldered together; of this there are examples among the Cyprinidæ, Fistularidæ, and Siluridæ.

Those vertebræ which are situated above the abdominal cavity have transverse processes developed to a greater or less extent. These, in some instances, as, for example, in the Cyprinidæ, remain for a long time only attached by suture to the bodies of the vertebræ, from which they are easily distinguished.

In certain Fishes, as, for example, in Merlus, the transverse processes are very large and give attachment to the swimming bladder. Sometimes the ribs are suspended from the transverse processes, or sometimes they are derived immediately from the bodies of the vertebræ. In this respect there are great varieties.

In those vertebræ that are situated behind the abdominal cavity there is an inferior foramen for the lodgement of the great blood-vessels of the trunk bounded by inferior spinal laminæ (*hæmapophyses*), and, like the superior, generally supporting long spinous processes, (*fig.* 493, 5,) so that the vertebræ seem to consist of similar parts, both above and below the body.

These inferior arches of the caudal vertebræ are considered by Cuvier as being formed by the inordinate developement of the transverse processes, which he describes as here becoming directed downwards and united to each other, so as to form the inferior ring; and, certainly, in the generality of Fishes, by tracing the apparently gradual conversion of the abdominal into the caudal vertebræ, such is the conclusion at which the comparative anatomist would naturally arrive. In many Fishes, however, as, for example, in the Murænidæ, these inferior arches with their appropriate spines are in the caudal region co-existent with distinctly developed transverse processes, evidently shewing that they must be regarded as being totally different elements of the skeleton, namely, the hæmapophyses. (See Osseous System.)

The inferior or hæmapophysial elements, like the superior arches, have in many instances oblique processes developed from them, which in some cases are very large and branched, so as to form a kind of interlacement around the vascular canal. This is especially observable in certain *Tunnies.*

As the vertebræ approach the tail, their processes are gradually shortened, and the vertebral canal becomes narrowed or obliterated, (*fig.* 493, 8,) and at length the terminal vertebræ have their apophyses consolidated with each other and with the interspinous bones, so as to form in some Fishes, as the Perch, a vertical triangular plate, to the posterior margin of which are articulated the rays of the caudal fin (9). In Fishes with long and pointed tails like the Eels this disposition is wanting; but in other races, such as the Pike, the real composition of this part of the skeleton is easily recognisable.

Ribs and sternum.—The ribs of Fishes have nothing to do with respiration, merely serving to support the muscular parietes of the body; they consist of the dorsal portion only, which is articulated by a single head, either to the transverse processes or to the bodies of the vertebræ themselves. Frequently they give off long bony processes, which penetrate among the muscles; and sometimes also similar processes are attached above the ribs to the bodies of the vertebræ themselves, so that the flesh of some Fishes appears full of little bones as fine as hairs. The ribs vary extremely in different genera. Sometimes they are round and slender, sometimes compressed and falciform; occasionally they seem to surround the whole abdomen, and in many species are quite rudimentary or altogether wanting. The *sternum* is entirely deficient in most Fishes; sometimes, however, it does exist, as in *Clupea*, *Vomer*, &c.; in such cases it consists of a longitudinal series of impair bones, differently shaped in different genera, to the sides of which the ribs are attached inferiorly.

Cranium.—The cranium of osseous Fishes, when all its parts are completely developed, is made up of no fewer than twenty-six bones, six of which are azygos, viz. the *basilar*, the *principal sphenoid*, the *anterior sphenoid*, the *vomer*, the *ethmoid*, and the *interparietal* or *superior occipital;* and twenty are in pairs, namely, the *frontal*, the *anterior frontal*, the *posterior frontal*, the *parietal*, the *mastoid*, the *external occipital*, the *lateral occipital*, the *petrous*, the *great alar* and the *lesser alar* bones; but as these have all been described and figured in a preceding article, and their homologies with the cranial bones of the other vertebrate classes fully discussed, (vide Osseous System, Comp. Anat., vol. iii. p. 826,) it would be superfluous to dwell upon them more at length in this place.

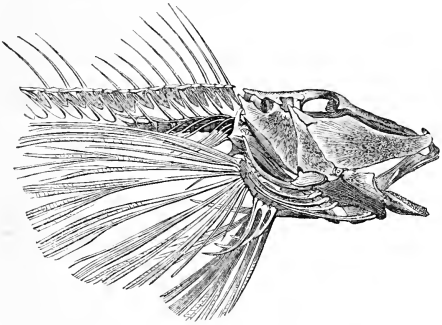
Bones of the face.—The bones of the facial apparatus have likewise been pointed out and figured in the article above referred to. They consist, when the series is complete, of the following pieces, which, seeing the extremely various forms of the face in this class of animals, present innumerable varieties as regards their developement and relative importance, notwithstanding that their general arrangement is tolerably persistent throughout the class.

The *maxillary* (*fig.* 436, 18, vol. iii. p. 826) and the *intermaxillary* (*fig.* 436, 17) form the anterior boundaries of the face and circumscribe the anterior and lateral limits of the mouth: the latter, however, is in Fishes the most important bone of the two, and is most commonly armed with teeth, while the former is very generally destitute of dental organs, and being imbedded in the fleshy substance of the upper lip, has been called by some authors the labial bone or os mystacis. It is indeed upon the relative shape and size of the intermaxillary bone that the form of the upper jaw of Fishes principally depends, and in some cases, as for example in the *Sword-fish* (Xiphias), *Lepidosteus*, &c. these bones are enormously prolonged anteriorly, so as to form an elongated beak or powerful rostrum which constitutes a formidable offensive weapon.

The face of Fishes, properly so called, is made up of several bony pieces very variable both in their size and number, which have been named the *prænasal* (*fig.* 436, 20,) the *suborbital* (*fig.* 436, *g*, *g*, *g*,) and the *supra-temporal* bones; all of these, however, with the exception perhaps of the prænasal, belong to the exoskeleton (vide vol. iii. p. 845.) In the hard-cheeked Fishes ("joues cuirassées" of Cuvier) these osseous plates are enormously developed, and indeed form a kind of bony mask enclosing all the muscles and other soft parts of this region of the head.

The Triglæ or *Gurnards* offer the best examples of the "hard-cheeked Acanthopterygii," which owe their name to the following arrangement of the above mentioned osseous pieces. The first suborbitals are of enormous size, entirely covering the face, articulating in front with the bones of the snout, and posteriorly with the preoperculum and two smaller suborbitals placed

Fig. 492.

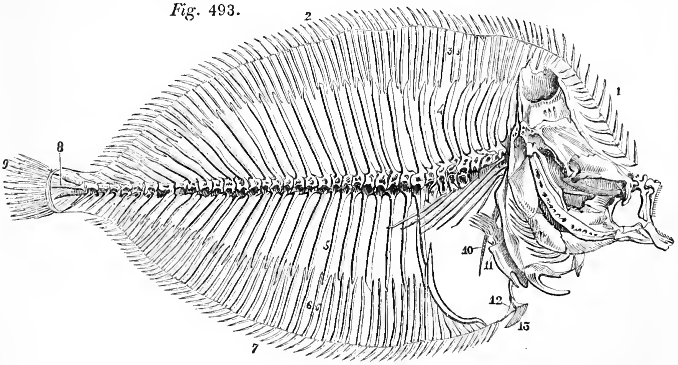


Skeleton of Trigla lyra, showing the bones of the face and the pectoral fin rays.

at the posterior angle of the orbit. Its articulation with the preoperculum is accomplished by means of an immoveable suture, so that the suborbital bones and the preoperculum must move together. The upper part of the face, moreover, is formed by the immoveable consolidation of the anterior frontals with the anterior extremity of the prænasal bones, which expand into a disc, and in some instances of the vomer likewise, which is slightly visible beneath the skin between the ossa nasi. All these bony pieces, as well as those composing the upper portion of the cranium, are hard, granular, and often armed with spines and cutting edges, so that few Fishes have their heads so well defended against the attacks of their foes.

The *Pleuronectidæ*, or Flat-fishes as they are commonly called, offer a most remarkable exception to the usual arrangement of the bones of the face, which exhibits a want of symmetry unparalleled in any other vertebrate animals. In this family, which includes the *Turbot*, the *Plaice*, the *Sole*, and others similarly organized, the whole trunk of the body is so much compressed laterally that such fishes, instead of swimming in the usual position, lie upon their left sides —a circumstance which, added to the singular fact that the right side is equally coloured both upon the dorsal and ventral regions, while the opposite is entirely white, has given rise to the vulgar supposition that the white surface is the ventral and the coloured the dorsal region of the fish —an error of which the anatomist is immediately made aware by a simple inspection of the skeleton (*fig.* 493). But in the construction of the head, by a strange apparent distortion of the elements composing the face and cranium, both eyes are allowed to be situated upon the right or upper surface of the body. This remarkable result is entirely due to the suppression of those processes and bones on the left side of the head which normally constitute the orbital cavity, whilst on the right side they are permitted to attain a very complete developement. The principal frontal bone (*figs.* 436, 437, 1, vol. iii. p. 826–7), which in all Fishes is azygos, occupies its usual situation, but whilst on the left side it is flat and bounded by a nearly straight margin, on the right side of the mesial line it presents as usual the processes which form the roof and posterior boundary of the orbit. The outer margin of the orbital cavity is formed by one large bony piece, the representative of the sub-orbital chain of bones, (*fig.* 436, *g g g*)

Fig. 493.



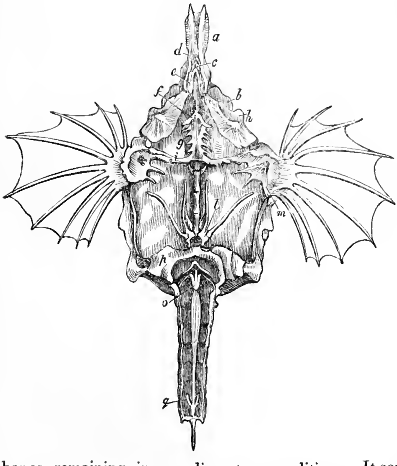
Skeleton of the Sole.

which does not exist at all upon the opposite side of the head, while anteriorly the anterior frontals (2) and the nasal bone (20) complete this part of the face. An orbital cavity is thus constructed upon the right or upper side of the head of the Pleuronectidæ, which suffices for the lodgment of the two eyes, which thus take the only position in which both could be made useful.*

Another equally remarkable arrangement is observable in the construction of the jaws of the Pleuronectidæ, which are in many genera very unequally developed on the two sides of the median line, only in this case the preponderance of developement is just the reverse of what exists in the orbital portion of the face, for here the bones of the right or upper side are small, while those of the left or inferior half are of considerably greater size and strength. Moreover, the former are but sparingly furnished with teeth, while the latter support the chief part of the dental apparatus; so that by this structure the mouth becomes twisted toward the ground, and the teeth so disposed as to work most effectually in that direction.

In the Syngnathidæ, Ostracions, and other Fishes, where the exoskeleton is inordinately developed, so as to form a suit of bony armour in which the exterior of the body is completely covered, the endoskeleton is proportionately weak and imperfectly formed, many of the

Fig. 494.



bones remaining in a rudimentary condition. This is well seen in the osteology of the Flying Hippocamp, (*Pegasus draco*, *fig*. 494,) where the bones both of the head and trunk seem to perform quite a secondary part as contrasted with the dense tegumentary framework covering the body. The whole face seems to be composed of a kind of snout (*a*), derived from the external armour of the head, in which the orbits (*b*) are excavated, the intermaxillary bones (*d*) and the lower jaw (*e*) alone being recognisable. The gill covers (*h*) belong to the exoskeleton, while the hyoid apparatus (*f*) and branchial arches (*g*) are but very imperfectly formed. The osseous zone that sustains the pectoral fins consists of a single bone, which is so consolidated with the tegumentary skeleton as completely to separate the abdominal cavity from the branchial chambers; and in the piece *m*, which forms the basis of the fin itself, the usual divisions are quite undiscernible. The vertebræ, both of the back and tail, (*o*, *q*,) are reduced to mere bony rings, while the pelvic circle, (*p*,) that supports the abdominal fins, (*l*,) is, like the rest of the skeleton, firmly connected with the external bony armour.

In the construction of the *anterior extremities* a few peculiarities may be specified.

Certain genera, more especially the *Salmonidæ* and the *Cyprinidæ*, have attached to the radius and ulna upon their inner side a third bone, which by its anterior extremity is connected to the anterior margin of the *os humeri*, thus forming a kind of buttress to support the fin. In the *Siluridæ* there likewise exist three bones in the fore-arm which at an early period become consolidated to each other, probably on account of the great strength requisite in that race of Fishes to support the great spinous ray of the pectoral fin. In the *Murænidæ*, where there are but two bones, these are suspended to the arch of the shoulder at the point of junction between the scapula and the humeral bone. In species that have no pectoral fins the radius and ulna do not exist.

There still remains to be noticed a long styliform bone generally composed of two pieces (*fig*. 437, 49, 50, p. 827, and *fig*. 493, 10), of which the upper piece (49), more or less flattened in shape, is suspended from the os humeri (48), to the posterior and superior part of the inner surface of which it is adherent. This styliform bone runs backwards along the side of the body behind the pectoral fin, and is plunged to a greater or less extent amongst the flesh.* Some anatomists have regarded this process as the homologue of the clavicle, but from the position which it occupies, running backwards, it seems rather to represent the *coracoid bone*, which is in this case lost among the muscles on account of the want of a sternum to which it might be articulated. It sometimes happens that this bone unites with that of the opposite side, and occasionally is of such length and strength as to reach backwards as far as the commencement of the anal fin. A not less curious disposition of this bone is observed in *Batrachus*, where the superior division extends upwards beyond the humerus to be connected with the spinous process of the first vertebra.

* The above description of the structure of the face in the Pleuronectidæ is derived from a disarticulated skull of the Halibut, contained in the Museum of the Royal College of Surgeons in London.

* Cuv. Hist. des Poissons.

In the *Cyprinidæ* this bone is of very rudimentary size, and is totally wanting in the *Murænidæ*, the *Anarrhicus*, and the *Siluridæ*.

The carpal bones, which support all the rays of the pectoral fin except the first, are generally placed, as above described, in a single row consisting of four or five pieces, but occasionally each of these bones presents a constriction near its middle, so as to have the appearance of being divided into two.

It is the bones of the carpus, and not those of the arm or fore-arm, which are elongated to give the pediculated structure to the feet of the frog-fishes, making them look like arms. In *Lophius* these are only two in number; in Polypterus there are three, and in Batrachus five. In these Fishes the radius and ulna are reduced to a very small size.

Posterior extremity.—The os innominatum, the femur, the bones of the leg and of the tarsus, are all represented in the osseous Fishes by a single bone (*fig.* 493, 12) of a triangular shape, and presenting several processes and prominent lamellæ. The apex of this triangle is directed forwards, and in the subrachial Fishes is attached in the angle formed by the junction of the two ossa humeri (11), at the point where the latter bones are united to each other by symphysis beneath the throat. In the true abdominal Fishes the pelvic apparatus is unattached to any part of the skeleton, being simply imbedded in the muscles beneath the belly.

The posterior extremity of the piece last mentioned gives attachment to the rays of the ventral fin (13), at the inner margin of which it not unfrequently gives off a long process extending backwards. The two pelvic pieces of the opposite sides are most frequently united to each other by a suture; but it sometimes happens that they remain partially separated either towards their anterior part, as in *Lophius*, or posteriorly, as in *Batrachus*.

Many Fishes, as *Muræna*, *Gymnotus*, *Xiphias*, &c. have no ventral fins, and in such cases the pelvic apparatus is altogether wanting.

Fin rays of the extremities.—These rays, with the exception of the most external one belonging to the ventral fin, are all soft and composed of numerous articulations, but towards their base they are more compact than elsewhere, the articulations being there scarcely visible. The base of each ray is enlarged so as to permit of its being firmly attached to the radial bone and to those of the carpus and pelvis.

The first ray of the pectoral fin is rarely branched, and its articulations are sometimes so completely consolidated as to simulate a spinous ray. This is the case, for instance, in *Silurus* among many other Fishes; but in such cases they are not really spinous rays in spite of their near resemblance, but derivations from the dermal skeleton, so that such Fishes are in all respects strictly malacopterygious.

Vertical fins.—The vertical fins of the osseous Fishes, namely, the dorsal, the caudal, and the anal fins, cannot be compared to any portions of the skeletons met with in other Vertebrata. They belong, in fact, to the exoskeleton (see Osseous System), but are so intimately related to the real bones both in structure and office, that they must be described in this place as being essentially connected with the bony framework of the body.

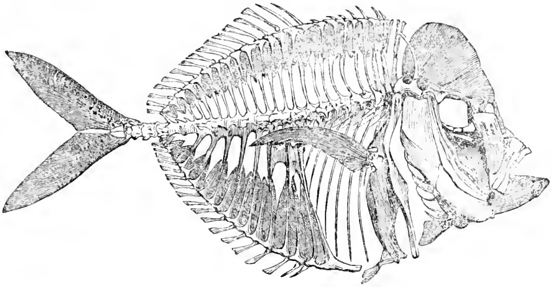
Every one of the vertical rays entering into the composition of these fins consists of two portions, an *interspinous bone*, which is imbedded in the flesh of the fish between the great lateral muscles, and serves as a basis to which the ray is attached, and the ray itself, which is visible externally and generally assists in supporting the membrane of the fin.

Interspinous bones.—The interspinous bones form a series reaching along the back to an extent proportioned to the length of the dorsal fin, and in a similar manner are appended beneath the post-abdominal region of the ventral surface coextensively with the anal fin, which they resemble. Each interspinous bone (*fig.* 493, 3, 3, 6, 6) resembles in its shape the blade of a dagger plunged into the flesh, while its head corresponding with the handle of the dagger remains on a level with the skin to give attachment to the base of the ray. This portion of the interspinous bone has an apophysis conjoined with it by suture, which in many instances is prolonged into a point that is connected to the articulation of the next ray of the fin. The interspinous bones are generally so disposed that their points penetrate between the spinous processes of the vertebræ, each being attached to these processes by a ligamentous membrane; but there are some Fishes, as the *Pleuronectidæ* (*fig.* 493), and (as regards the composition of the anal fin) the *Siluri*, in which there are two interspinous bones to each spinous process, and in other cases the relations between the two become quite lost, as, for example, where three or even four spinous processes are interposed between some of the vertebral spines, a fact which in itself is sufficient to disprove the hypothesis of Geoffroy, extensively promulgated in this country by the writings of Professor Grant, namely, that the interspinous bones of Fishes are dismemberments of the spinous processes, one-half of the latter becoming displaced and forming the interspinous bone as well as the ray which it supports.

On this point Cuvier remarks that in many genera, such as Muræna, Ophicephalus, and Gymnotus, the inferior interspinous bones are separated from the vertebræ by the cavity of the abdomen, which is prolonged to a considerable distance beyond the commencement of the anal fin; whilst in other cases, as in the Pleuronectidæ, there are interspinous bones even upon the cranium (*fig.* 493, 1). These circumstances, joined to the fact that in those portions of the back or of the tail which have no fins attached to them there are generally no interspinous processes although there are vertebral spines, make it impossible to regard the bones in question as being derivations from the vertebral column.

Rays of the vertical fins.—Each fin-ray (*fig.* 493, 2, 7) is connected with its corresponding interspinous bone by a ginglymoid articulation. The rays are of two kinds: *spinous rays*, such as

Fig. 495.



Skeleton of Lampris guttata, showing the interspinous bones, easily recognisable from their dark tint.

are met with in acanthopterygious Fishes, and *branched* or *soft rays*, such as are found in the Malacopterygii. They are all divided by a longitudinal raphé, or suture, into two lateral halves, so that each appears to be formed of two rays conjoined,—a circumstance which forms an additional argument against these parts of the skeleton being dismemberments of the vertebræ.

The rays of the caudal fin are always soft and articulated; but in many Fishes some of those at its root, both above and below, are gradually diminished in size until nothing is left of them but the hard part forming the base.

Skeletons of Chondropterygii.—In the true cartilaginous Fishes, such as the *Sharks* and *Rays*, the bones are always destitute of those osseous fibres which give hardness to the skeleton in the preceding races possessing a true bony skeleton. Their interior remains permanently soft and cartilaginous, while their external surface is strengthened by becoming encrusted with a layer of granular-looking calcareous matter.

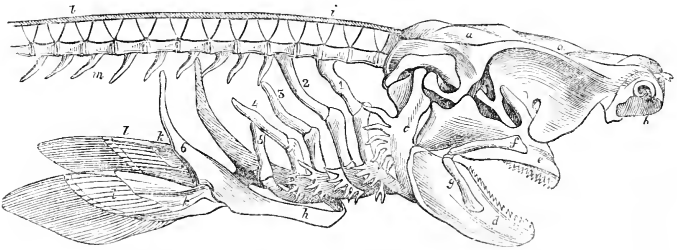
As there is in the Chondropterygii no deposition of bony particles radiating from ossific centres, there can be no division of the cranium into distinct bones, nor of course any sutures: the whole cranium consists of a single cartilaginous piece, in which, however, it is easy to distinguish the same regions, the same fossæ, the same eminences, and the same holes as in the skull of one of the osseous Fishes; but, although it is not difficult with a little attention to point out the situation of the different bones, to define their limits is impossible.

The bones of the face are likewise consolidated with the great cranial mass, and consequently are quite undistinguishable except from their position in relation to organs into the composition of which they enter.

The structure of the skull therefore appears exceedingly simple when compared with that of an osseous fish. The whole pterygo-temporal apparatus is represented by two pieces, one of which corresponding with the temporal, tympanic, symplectic, and jugal bones of Cuvier, or the tympanic pedicle, as Professor Owen calls the long stem, which in the osseous Fishes is composed of those elements, is here represented by a single piece (*fig.* 496, *c*) interposed between the side of the cranium and the point of junction between the upper and lower jaws—an arrangement precisely similar to that which is observable in the Batrachian Reptiles.

The other piece belonging to the pterygotemporal apparatus (*fig.* 496, *e*) forms, in conjunction with its fellow of the opposite side, almost the whole of the upper jaw, covering

Fig. 496.



Anterior portion of the skeleton of a female Shark (Acanthias niger).

a, a, cartilaginous skull; *b,* nasal cavity; *d,* lower jaw; *e,* upper jaw; *f, g,* connecting pedicle; 1, 2, 3, 4, 5, branchial apparatus; 6, *h,* zone supporting (*k, l,*) pectoral fins.

the greater part of the roof of the mouth, and likewise supporting all the formidable teeth with which this jaw is armed. Posteriorly it gives attachment to the inferior maxilla by two large articulating surfaces, and above it is only connected to the skull by the muscles implanted into it. From its upper margin it gives off a process, shown in the figure, which remains permanently cartilaginous, and in the living state is imbedded among the muscles that form the inner wall of the orbit; the whole is thus left completely moveable so as to give great latitude to the motions of the jaws.

The *superior maxillary bone (fig.* 497, *d*) and the *intermaxillary bone* (*c*) are of very small size, being merely imbedded in the substance of the upper lip and connected superiorly by ligament to the face and the piece last described. Inferiorly these bones are attached to a third (*fig.* 497, *e*,) which is fixed by ligaments to the outer

Fig. 497.

a, nasal cavity; *b*, olfactory organ; *c*, superior labial or intermaxillary cartilage; *d*, intermaxillary bones; *e*, inferior portion extending between the preceding and the lower jaw; *e, e, e, e*, central sternum-like pieces; *f. f, f, f*, branchial arches; *i, i, i*, branchial appendages; *k*, scapular zone; *l, m, n*, pectoral fins.

surface of the lower jaw at about one-fourth part of its length from the symphysis, so that the three together form an osseous and ligamentous band that circumscribes the angle of the mouth and materially diminishes the *rictus* of the jaws. The inferior piece (*e*) is most probably one of the elements belonging to the lower jaw detached from its usual connections with that bone.

The *inferior maxilla (fig.* 497, *f)* consists of two lateral halves united by a symphysis; each half consists of a single piece of considerable breadth, presenting a deep sulcus superiorly for the lodgement of the teeth.

The *branchial apparatus* is placed further back than in the osseous Fishes, being situated beneath the commencement of the spine—a circumstance which causes the bones of the shoulder to recede backwards also.

The whole of the opercular apparatus is wanting in the cartilaginous Fishes with the exception of the Sturgeons (*Sturionidæ*), which seem in many respects to occupy an intermediate place between them and the osseous division.

The *os hyoides* in *Squatina* and the Sharks generally is composed of three pieces, one situated in the mesial line, and two lateral branches. The mesian piece or body of the os hyoides corresponds to the bones of osseous Fishes; while the large rami, instead of mounting up to be connected with the styloid bones, terminate immediately behind the articulation of the lower jaw, with which they are intimately connected by means of strong ligaments. From its posterior margin branchiostegous rays are given off precisely as in the former group, but these have nothing to do with the formation of an opercular flap, the branchial apertures being here of a very different character.

The branchial arches in their general arrangement resemble those of the osseous Fishes, but there are nevertheless important differences to be remarked. In *Squatina* there exists inferiorly a kind of sternal apparatus which occupies the mesial line. This consists posteriorly of a central piece (497, *e, e, e*,) that very nearly resembles a broad spear-head, forming a kind of sternum, the handle of the spear closely representing the xiphoid cartilage of the human sternum; and in front of this are three pieces on each side, something like the costal cartilages. Of these the anterior pair are united to each other in the mesial line, while the second and third are fixed to the sides of the central piece first mentioned. The arches supporting the branchiæ are five in number on each side, (*fig.* 497, *f, f*) each consisting of an inferior and superior portion connected with each other by moveable articulations. The inferior portion consists of a single piece, the superior of two, united together by ligaments. The anterior arch is connected by ligaments to the body of the os hyoides, and also to the central pieces. The four posterior are attached by ligament to the succeeding lateral processes of the sternal apparatus, and thus a framework is formed that almost entirely surrounds the neck. The superior extremities of these arches are fixed beneath the anterior vertebræ of the spine by a loose ligamento-cellular substance.

In other Sharks and in the Rays (*fig.* 496, 1, 2, 3, 4, and *fig.* 500, 3, 4, 5) the ossification of these pieces is very imperfect; the branchiæ, in the latter more especially, being almost entirely sustained by membranous structures.

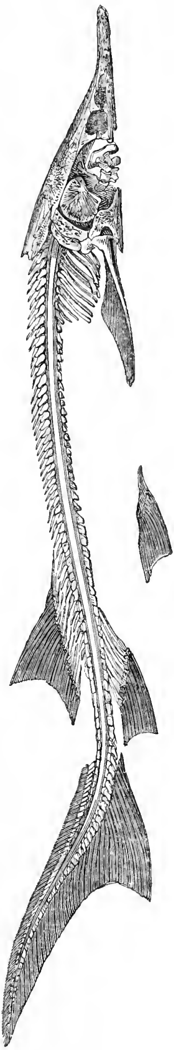
The *pharyngeal bones* in the true Chondropterygii are totally wanting.

In some Sharks, as, for example, in *Galeus*, there are vestiges of a true *sternum* situated below the branchial apparatus, from the anterior edge of which it is suspended by ligamentous attachments, while posteriorly it is connected with the centre of the zone, to which the pectoral fins are attached. To the sides of this sternum are appended five or six pairs of sternal ribs, but the ossification of these bones, as well as of the sternum itself, is very incomplete.

The *vertebral column* of the cartilaginous Fishes presents two or three very remarkable peculiarities. In the Ray-tribe (*fig.* 500, 6) all the vertebræ of the anterior portion of the spine for a considerable distance are immoveably fixed together by an incrustation of earthy matter that forms a kind of tube or sheath in which they are encased, the number of vertebræ thus anchylosed to each other being only indicated by the foramina through which the spinal nerves make their escape.

Another peculiarity is that both in the Sharks and Rays there are twice as many superior vertebral laminæ as there are vertebræ. This is owing to the developement of spinal laminæ to cover the intervertebral spaces, in addition to those which constitute the spinal canal in other vertebrata.

Fig. 498.



Skeleton of Sturgeon (Accipenser Sturio).

To the transverse processes of the vertebræ covering the abdomen rudiments of *dorsal ribs* are appended. In the Raidæ, however, these are very small; but in Sharks, (*fig.* 496, *m*,) and more especially in the Sturgeons (*fig.* 499, *b*, *c*,) they attain considerable dimensions.

Along the whole length of the post-abdominal region of the vertebral column there are developed hæmapophysial arches and inferior spinous processes, but the latter are always exceedingly short and imperfectly formed. This is well seen in the Sturgeon (*fig.* 498), in which fish, although the central portion of the vertebral column remains permanently cartilaginous, the hæmapophysial arches and spines are distinctly bony.

There are no interspinous bones, the dorsal and anal fins being only connected to the spinous processes of the vertebræ by broad ligamentous expansions. The structure of the caudal fin is likewise very different from what is met with in the osseous Fishes. In the Sharks and Sturgeons, (*fig.* 498,) which have the tail deeply furcate, the vertebral column is continued into the upper portion along its entire length, the caudal fin being entirely supported by long rays connected both superiorly and inferiorly to the extremities of the spinous processes of the individual vertebræ.

The framework to which the anterior extremities or pectoral fins are attached is a strong osseous zone which encircles the body immediately behind the branchial apparatus. This zone consists superiorly of the *scapular* and *supra-scapular* pieces, and inferiorly of a broad osseous belt (*fig.* 497, *k*,) which encloses the fore part of the abdominal cavity, representing the *coracoid* and *clavicular apparatus* of the Reptilia. In the Raidæ the supra-scapular pieces are inseparably connected with the spinous processes of the dorsal vertebræ, but in the different races of Sharks they are loose and unattached. At the junction between the dorsal and abdominal portions of the above zone are attached by strong articulations the pieces which support the rays of the pectoral fin. These pieces represent the whole brachial and carpal apparatus of the higher Vertebrata. In the Rays these are of enormous dimensions, (*fig.* 500, 8, 9, 10, 11) extending posteriorly so as almost entirely to surround the cavity of the abdomen, whilst anteriorly they are prolonged in a similar manner in front of the cranium. To the external aspect of this vast carpus are attached upwards of a hundred fingers supporting the enormous pectoral fins, which here form by far the greater portion of the body, giving it that square shape for which these Fishes are so remarkable. Towards the circumference of the body each of the fin-rays bifurcates (12), so that the total number of phalanges entering into the composition of this prodigious hand is one of the most remarkable facts in comparative osteology.

Fig. 499.

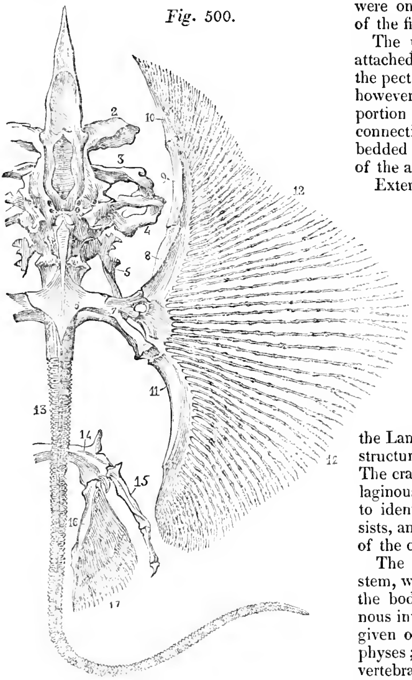
Fig. 500.



Skeleton of Ray.

1, snout; 2, 3, 4, 5, branchial arches; 6, consolidated anterior vertebræ; 7, humeral apparatus; 8, 9, 10, 11, carpus; 12, fin rays; 13, posterior detached vertebræ; 14, pelvic apparatus; 15, clasper; 16, tarsus; 17, fin rays of posterior extremities.

The pectoral fins of the Sharks (*fig.* 496, 497) and Sturgeons (*fig.* 498) are formed after the same plan as that of the Skate, only upon a considerably smaller scale, representing as it were only a moiety of the posterior division of the fin of the preceding genus.

The posterior extremities or ventral fins are attached to a zone similar to that which supports the pectorals (*fig.* 500, 14). The pelvic zone is, however, very incomplete, the superior or iliac portion being quite deficient, so that it has no connection with the spine, but is simply imbedded among the muscles at the posterior part of the abdomen.

Externally the pelvis supports the first ray of the ventral fin (*fig.* 500, 15), which is very large, and likewise a long stem (16) composed of numerous articulations, to the commencement of which the succeeding fin rays are appended. Inferiorly the former is prolonged in the male Rays into a very curious club-shaped apparatus called the "clasper," of the nature of which we shall have occasion to speak further on.

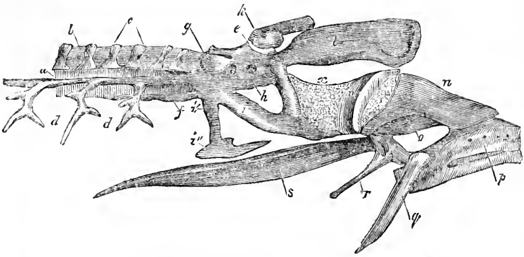
Skeleton of Dermaptcrygii.—In the cyclostomatous Fishes, such as the Lamprey, the skeleton is of still more simple structure than in the plagiostomatous genera. The cranium exhibits through life a soft cartilaginous texture; nevertheless it is not difficult to identify the different pieces of which it consists, and to point out their analogies with those of the osseous Fishes.

The spine consists of a soft cartilaginous stem, which passes along the entire length of the body. It is enclosed in a strong membranous investment, from which prolongations are given off that perform the office of spinal apophyses; but the only indications of distinct vertebræ exist in the presence of slight and almost imperceptible rings of osseous substance distinguishable upon the surface of the cartilaginous stem above mentioned.

The Cyclostomata have neither pectoral nor ventral fins, so that in this respect they are the most imperfect of all Fishes: even the vertical fins situated above and beneath the tail are only supported by a few soft and scarcely sensible fibres representing the fin-rays.

The most remarkable part of the skeleton of the Lampreys (*Petromyzon*) is the cartilagi-

Fig. 501.



Skull of Sea Lamprey (Petromyzon marinus). After J. Muller.

a, cartilaginous spinal axis; *b, c*, rudimentary cartilaginous neural arches; *d, d*, part of cartilaginous respiratory framework; *g*, auditory capsule; *h*, cranium; *i, i'', i'*, processes therefrom giving attachment to the muscles of the tongue; *k*, nasal capsule; *l*, cartilage covering hinder part of mouth; *n, o, p, q*, anterior cartilages entering into composition of mouth; *r, s*, os hyoides.

nous framework situated on the sides of the neck, enclosing the branchial apparatus, and allowing respiration to be accomplished by a peculiar mechanism which will be described in its proper place. This singular structure consists of seven pairs of cartilaginous arches derived from a kind of sternum situated in the mesial line beneath the throat. These arches, which have nothing in common with the branchial arches of Fishes, mount upwards interruptedly towards the spine, giving off anterior and posterior processes to form a kind of frame to the branchial orifices. Anteriorly this remarkable apparatus is attached to the cranium, while posteriorly it terminates in a thin cartilaginous capsule, which encloses the heart; it will, however, be better to describe it further on.

In *Ammocetes* the skeleton is even more imperfect than in the Lamprey, all its parts remaining permanently in a membranous condition, so that they would seem to resemble worms more than vertebrated animals, and in fact were absolutely classed as worms even by the great Linnæus.

Skeleton of Branchiostoma.— In this remarkable Fish the entire spine is made up of a succession of very delicate membranous rings without any apophyses whatever; neither in young specimens is the slightest trace of a cranial dilatation of the vertebral column apparent, probably owing to its being at this period quite gelatinous in its texture, and consequently translucent; and even in adults such is its softness that it is impossible to distinguish it satisfactorily; but along the back from sixty to seventy vertebræ are easily counted, the divisions between them being indicated by slight bulgings and lines passing obliquely from above downwards on the sides of the column. In this way a separation between the rachidian rings is rather indicated than proved to exist; for, although there is, so to express it, a tendency to divide at the points indicated, the division is rather artificial than natural.

According to Mr. Goodsir, the chorda dorsalis is formed externally of a fibrous sheath, and internally of an immense number of laminæ, each of the size and shape of a section of the column at the place where it is situated. When any portion of the column is removed, these plates may be pushed out of their sheath like a pile of coins. They have no great adhesion to one another, are of the consistence of parchment, and appear like flattened bladders, as if formed of two fibrous membranes pressed together.

Two ligaments may be detected, one running along the upper, the other along the lower aspect of the spinal column; and from its sides aponeurotic laminæ pass off to form septa of attachment between the layers of muscles. Along the mesial plane above the column a similar aponeurosis separates the superior lateral muscular masses, and by splitting inferiorly, so as to join the sides of the rachidian chord, forms the canal for the spinal medulla. Foramina exist all along this canal for the passage of the nerves. A similar aponeurotic septum is situated along the inferior part of the column from the anal opening to the extremity of the tail. Imbedded in these two aponeuroses are cartilaginous rudiments representing the superior and inferior vertebral spines, but these are of extreme softness and delicacy; and the traces which exist of the transverse processes and ribs are in the same soft condition, so that they are with difficulty distinguishable. In Branchiostoma, therefore, the locomotive skeleton may be said to consist of the vertebral column only, without either cranium or appended limbs.

There is, however, an exceedingly elaborate framework of soft cartilaginous arches which surrounds the branchial chamber, and forms a kind of branchial thorax, the nature of which will be examined further on.

Arthrodial system.—The articulations of the bones of Fishes present the same varieties as those of other animals; only the arthrodial and ginglymoid are more rarely met with because their limbs have not to execute such complicated movements.

It is by means of a ginglymus that the lower jaw and operculum are attached to the pterygo-palatine apparatus, and the latter to the cranium. The same articulation occurs between the rays of the dorsal and anal fins with the interspinous bones, and between the first ray of the pectoral fin with the bone analogous to the radius.

There are, moreover, in Fishes two kinds of articulations having determinate movements which are not met with in the other classes: one is formed by two rings joined one to the other, as those of a chain, and another, which at the will of the fish becomes very moveable or very fixed. We find examples of both these in the family Silurus.

The articulations with determinate movements offer ligaments, cartilaginous surfaces, and a synovial fluid, as in higher animals.

The articulations between the bodies of the vertebræ are effected by means of a fibro-cartilaginous substance which traverses the bodies, and which sometimes, as in the Sturgeon and the Lamprey, takes the form of a long cord.

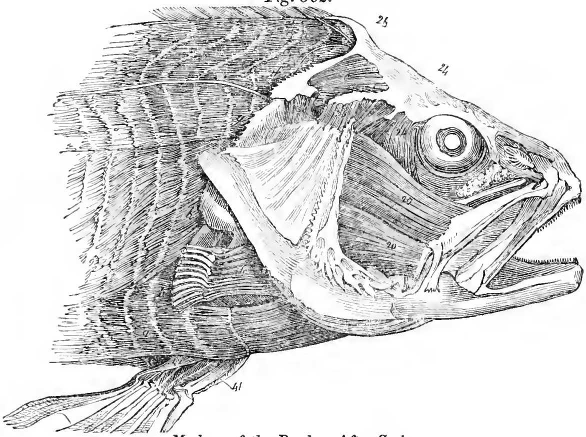
The articulations of the opercular bones between themselves, the pieces composing the branchial apparatus, the bones of the shoulder, of the arm, of the carpus and pelvis, and of the last to the shoulder, are effected by means of interposed fibro-cartilaginous substance.

Muscular system.—The general character of the myology of Fishes has been treated of in a preceding article, (Muscular System, Comp. Anat.) It will therefore only remain for us in this place to give such an account of their arrangement as the limits of this article permit, dividing them into groups so as to facilitate reference to the accompanying figures, representing the dissected muscles of the Perch, as described by Cuvier.

The *great lateral muscles* on each side of the trunk of the body form a mass that extends from the back of the head and posterior surface of the pectoral zone all the way to the sides of the base of the caudal fin. These two great muscles are divided transversely by aponeurotic laminæ into as many layers of fibres as there are vertebræ, giving the flaked appearance to the flesh of Fishes, (*fig.* 502, *f*, *g*, *h*,) and are connected to all the vertebræ and vertical processes of the spine as well as to the interspinous bones.

Superior and inferior slender muscles of the trunk.—These are situated in the interspace between the lateral muscles, both along the middle of the back and also of the ventral aspect of the body.

Fig. 502.



Myology of the Perch. After Cuvier.

Proper muscles of the fins.—In the caudal fin these are of three kinds, some being superficial, others deep-seated, and a third passing from one ray to another.

In the dorsal and anal fins the arrangement of the proper muscles is very simple, because they are all disposed uniformly, each fin-ray having six, viz. four deep-seated and two superficial.

The superficial muscles are inserted into the fin-ray at its base, one on the right and the other on the left side, and serve to move it in corresponding directions. The deep-seated set (*figs* 505, 3 and 4) arise from the interspinous bones, and are inserted into the anterior and posterior aspects of the base of the ray, serving to elevate or depress it vertically.

The movements of the shoulder are effected by the great lateral muscles inserted into them, or by strips derived therefrom.

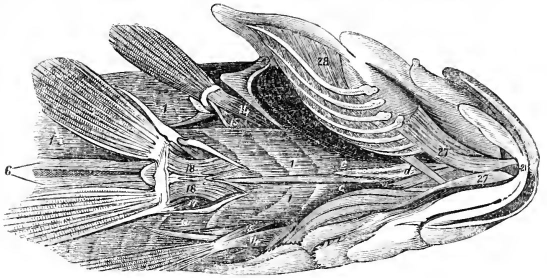
The muscles of the pectoral fins (*figs.* 502, 503, 505, 14, 15, and 16) are inserted into the fin-rays, which they serve to elevate or depress at pleasure.

The muscles of the ventral fins, (*fig.* 503, 17 and 18) arise from the pelvic bone, and serve to expand or advance the fin-rays of the abdominal members.

The muscles of the jaws are represented by a large mass, (*fig.* 502, 20, 20,) derived from the palato-temporal arch and the anterior edge of the preoperculum, which is inserted into the lower jaw, and serves to close the mouth; an arrangement very different from that of the temporal and masseter muscles of the higher vertebrata.

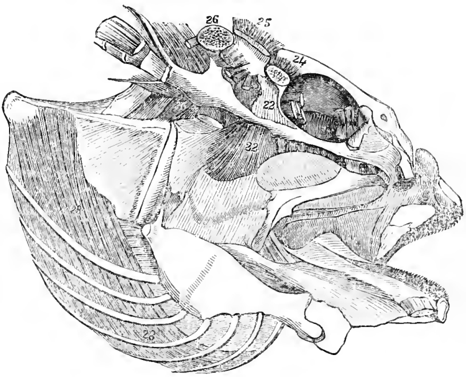
Muscles of the palato-tympanic arch consist of a *depressor*, (*fig.* 504, 22,) derived from the

Fig. 503.



Myology of the Perch. After Cuvier.

Fig. 504.



Myology of the Perch. After Cuvier.

sphenoidal and alar bones; and an elevator, (*fig.* 502, 24,) which comes from beneath the orbit, and antagonizes the preceding by dilating the cavity in which the branchiæ are lodged; these two are the principal muscles employed in respiration.

Muscles of the operculum.—The movements of the operculum are very similar to those of the palato-tympanic arch, and its muscles likewise consist simply of an elevator and a depressor (*figs.* 504 & 505, 25, 26.)

Muscles of the os hyoides.—The principal of these (*figs.* 503 & 505, 27) seems to correspond to the *genio-hyoideus*, and has a similar office; its antagonist is a prolongation of the great lateral muscle of the body (*fig.* 503, 1, 1.)

Muscles of the branchiostegous membrane.—These consist of a layer of fibres (*figs.* 503, 504, 28) running transversely across the inner surface of the branchiostegous rays; this is in some Fishes assisted by accessory muscular fibres derived from the os hyoides.

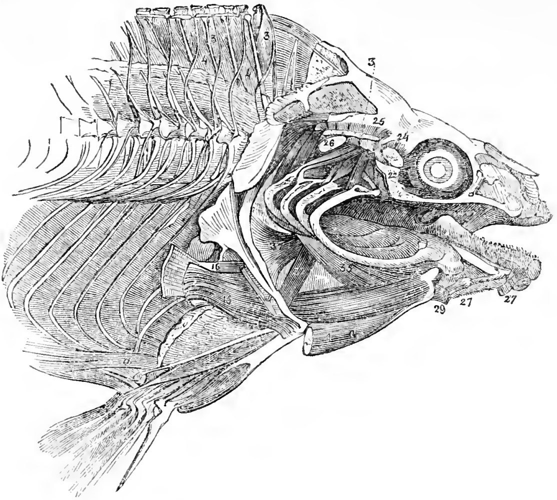
Muscles of the branchial and pharyngeal apparatus.—These must be divided into several groups, some of which connect this apparatus with the skull, others to the spine, others to the humeral bone, and others to the os hyoides; while some connect one part of the apparatus to another. Their general distribution is shewn in *fig.* 505, 32, 35, 37, &c., but to describe them more minutely would carry us beyond our limits.

In the *Ostracions*, or box-fishes, which have their entire body, with the exception of their jaws and fins, enclosed in a dense case of armour, the arrangement of the lateral muscles of the trunk is considerably modified; they occupy, indeed, the same situation, but are only attached at the head and tail. In this case insertions into the vertebral column would have been useless, seeing that the tail is the only moveable part. The texture of these lateral muscles is also much simpler, their fibres being almost all longitudinal. The ribs are entirely wanting, these parts being replaced by a silvery aponeurosis, which forms the walls of the abdomen and lines the interior of the shell.

In the Plagiostome cartilaginous genera there are considerable differences in the arrangement of the muscular system which will demand a brief notice. The *Raidæ*, or *Skates*, for example, so remarkable for the construction of their skeleton, are not less so in respect to the disposition of the muscles that move its different parts. In these fishes the muscles of the trunk resemble very strikingly those which are met with in the tails of quadrupeds. They are four in number, arranged upon two planes, so that there are two superior lateral and two inferior lateral muscles.

The superior laterals arise from the middle portion of the vertebral column above the abdo-

Fig. 505.



Myology of the Perch. After Cuvier.

men by strong fleshy origins covered with dense aponeurosis. Above the pelvic arch they divide into numerous tendinous slips which run backwards in separate sheaths, each successively approximating the middle line of the body, where they are inserted on the dorsal aspect of each vertebra as far as the extremity of the tail.

The inferior lateral muscles, like the preceding, take their origin in the lumbar region, and present nearly the same arrangement, only their tendons are much more slender than those of the superior set. At their termination each tendon bifurcates, allowing that appropriated to the succeeding vertebra to pass through it so as mutually to form sheaths to each other, so that they are all, except the last, both *perforati* and *perforantes*.

Osseous Fishes have no special muscles appointed for the movements of the head, but in the Rays there are three destined to this office, one serving to move the head upon the trunk, the other two raising and depressing the extremity of their elongated snout.

The former is situated upon the upper aspect of the body above the branchial cavity. It arises from the vertebral column and from the anterior portion of the pectoral zone. Its insertion is into the posterior region of the head, which it raises towards the back.

Of the two muscles of the snout, the superior arises also from the scapular cincture by a short fleshy belly, from which a thin cylindrical tendon is given off. This runs in a mucous sheath, above the branchiæ to the base of the snout where it is inserted, serving of course to raise it upwards.

The other is situated beneath the body within the branchial cavity, where it arises from the anterior cartilages of the vertebral column. It runs obliquely outwards, and afterwards inwards, so as to describe a curvature, the convexity of which is external. Its insertion is almost entirely fleshy into the base of the rostrum, which it bends or curves towards the belly.

The muscles of the huge pectoral fins form two thick fleshy layers, covering these limbs both above and below, and dividing into as many fasciculi as there are fin rays, into which they are inserted. A similar arrangement exists likewise in the ventral fins, the representatives of hinder extremities.

The muscles of the jaws in the cartilaginous Fishes are more numerous than in those possessed of an osseous skeleton. The lower jaw of the Skate is depressed by a large oblong muscular mass, composed of straight parallel fibres, which, taking its origin from the anterior margin of the transverse cartilaginous belt that sustains the pectoral fins, runs forward to be inserted near the centre of the inferior maxilla, which it thus powerfully depresses.

Two small muscles, one on each side, contribute to the same effect. These are attached in front near the commissure of the lips, and running inwards, almost cross each other beneath the preceding, which is azygos; there they are attached partly to the skin, and partly to the transverse cartilage.

Those muscles which raise the lower jaw act likewise upon the upper. One attached to its lateral part mounts over the upper jaw, as over a pulley, and runs to be implanted above the upper jaw, which is here moveable, into the base of the cranium.

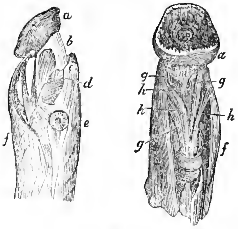
A second is broad and short. Its fibres are straight, parallel, and fleshy, passing from the superior margin of the upper jaw to the inferior margin of the lower.

The third presents a very singular arrangement, having its fibres interlaced in a very remarkable manner. These, however, may be divided into three principal masses, two of which are anterior and one posterior.*

One of these masses is situated in front of and above the upper jaw near the commissure. It is attached to its superior margin, and runs obliquely to join the external edge of the second mass. This latter occupies nearly the same position relative to the lower jaw; it passes behind the other and is conjoined with it externally. The third or posterior mass is derived from the end of the upper jaw, and joins the hinder margin of the second. All these fibres so singularly interlaced co-operate in holding the mouth closely shut when the Skate has seized its prey.

Lastly, there are two very long muscles derived from the spine, which pass between the palate and the cranium to be inserted into the upper jaw. These bring the mass of the mouth forward again after it has been retracted by the broad oblong azygos muscle above described, which passes between the pectoral zone and the inferior maxilla.

Fig. 507.

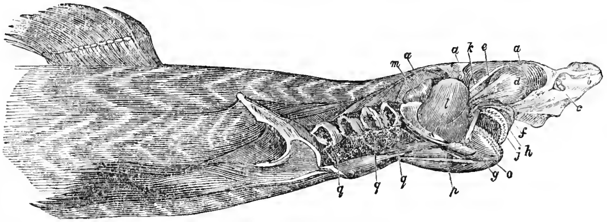


Head of Lamprey, after Carus, shewing muscles.

a, b, c, cartilages of the mouth; *d, e, f,* external muscles inserted into ditto; *g, h,* muscles derived from the hyoid apparatus.

In *Sharks* the lateral muscles of the body and fins resemble those of the osseous Fishes. Their jaws, however, constructed after the same principle as in the Skate, are equally moveable, and their muscles almost similar; only here, as their mouth is situated much nearer the anterior extremity of the skull, the two great muscles coming from the spine to the upper jaw are wanting.

Fig. 506.



Myology of Shark (Squalus glaucus). After Carus.

a, a, a, cranium; *b,* rostrum; *c,* olfactory organ; *d,* eye-ball; *e,* muscles of eye; *f,* upper-lip; *h, j,* teeth; *k,* lower surface of skull; *l, m,* muscular masses which close the mouth, resembling those of the Skate described above; *g,* broad muscle passing from upper to lower jaw; *p,* depressors of lower jaw, as in the Skate; *q, q, q,* entrances to the gill-chambers.

In the Lampreys (*Petromyzonidæ*) the oral sucker is moved by slips derived from the anterior temination of the great lateral muscle (*fig.* 507, *f*) as well as by a set of very strong fasciculi derived from the hyoid apparatus, which, by retracting the interior of the disc, cause the adhesion of the sucker, and move the different parts of the dental apparatus described in a preceding page, (*g, h, m.*) The action of these will, however, be better understood by inspecting the figures than by any detailed description.

Tegumentary system.—The essential character of the skin, says Agassiz,† is that it completely envelopes an animal, and thus forms a kind of external skeleton which protects it over its whole surface, as the osseous skeleton protects and supports the internal viscera. In the invertebrate races of animals there are no other solid parts except those which are produced by or connected with the tegumentary system, but which nevertheless can by no means be compared with the osseous system of the Vertebrata, which is quite peculiar to the latter, and has no analogy whatever with the solid framework of the inferior classes.

The skin, moreover, (observes the same illustrious author,) is not exclusively limited to the external surface of the body, but penetrates into and invests the internal cavities, on the inner surfaces of which it likewise produces solid structures of various kinds to which different offices are assigned, as, for example, the teeth and all the corneous pieces which in many classes are met with upon the lining membrane of the digestive tube. It

* Cuvier, Leçons d'Anatomie Comparée.

† Agassiz, Recherches sur les Poissons Fossiles, 4to. 1834.

therefore becomes necessary to distinguish two modifications of the dermal skeleton, one constituting the investments of the external surface of the body, the other developed from the internal surface. These two kinds of exo-skeleton exist simultaneously in all vertebrate animals in addition to the endo-skeleton or proper osseous system, which encloses the visceral cavities or affords a framework around which the soft parts are situated. In the vertebral division of the animal kingdom not only do these two modifications of the dermoskeleton present numerous connexions with each other, but they are likewise intimately connected with the osseous system, and in many parts of the body insensible transitions may be perceived between one and the other, as in Fishes, more particularly between the opercular bones and the scales, or between the latter and the bones of the occiput and humerus, or between the pharyngeal bones and the teeth. (See Osseous System, Comp. Anat. vol. iii., page 846.)

There exists, however, a constant antagonism in the developement of the three kinds of skeleton above indicated, some of the different parts of which attain to a more perfect growth in proportion as those of the other are less complete in the different regions of the body.

Before proceeding further with this subject, it will be necessary to examine with a little attention the structure of the skin itself preparatory to describing the various dermal appendages produced therefrom.

The skin of Fishes is always much more tensely stretched over the surface of the body than in other animals, and, being closely united to the subjacent muscles by dense cellular tissue, is never endowed with that mobility which is observable among many of the higher Vertebrata. As in other classes, the skin is composed of an epidermis which forms the external envelope of the body, of a *rete mucosum*, consisting of the internal stratum of the corneous epidermis, which as yet remains soft and covers the surface of the corium by which it is secreted; and lastly of the corium itself, or the internal living skin furnished with nerves and vessels by which the outer layers of the integument are secreted as well as the different colours that ornament the exterior of the fish.

The varied colours of the fish result in fact from the deposition of corresponding pigments between the epidermis and the true skin, and in the class before us these colouring matters are particularly abundant. In the first place the inner surface of the scales is imbued with a pigment of metallic splendour, and generally of a silvery or golden hue and of brilliant lustre, besides which, more especially towards the back and over the upper aspect of the body, are points or patches of black or diversely coloured pigments, which according to their abundance and character give the peculiar markings of the fish.

The material which gives this metallic lustre to the scales of Fishes, known in commerce under the name of "argentine," was minutely investigated by Reaumur,* who found that, when examined under high magnifying powers, it is composed of crystalline laminæ, divided transversely so as to form rectangular figures about four times longer than they are broad. These crystals he believed to be contained in vessels, or in delicate tubes of animal matter, mistaking for vessels the little bundles in which they are disposed.† These different pigments have been lately discovered to consist of extremely minute crystals of various earthy and metallic substances; they are met with even in the interior of the body, as for example, upon the external surfaces of the peritoneum, of the brain and medulla oblongata, and in the interior of the eyeball. Ehrenberg observed them in the Pike; but they are met with in all Fishes, and present numerous varieties of form and composition in different species. One very remarkable phenomenon connected with the colour of Fishes, and which apparently depends upon the abundance of these pigments, and the rapidity with which they are secreted and absorbed, is the change of colour which many species undergo at different periods of the year, as, for example, at spawning time; or during their growth, or even when excited to violent exertion, or lastly after their death, when they are exposed to different atmospherical influences. During the spawning season, observes Agassiz, the tints of all species hitherto observed are more vivid and distinctly marked than at other periods; but even whilst drawing living specimens, he has observed that, when suddenly irritated or whilst making violent movements to escape from the hand when seized, these colours suddenly become much deeper and more brilliant, after which they become completely pale, and only return by slow degrees; a phenomenon which the writer above quoted supposes to depend upon a sudden exuberant secretion and subsequent absorption of the coloured pigments.

The surface of the body of living Fishes is moreover constantly lubricated by a great quantity of mucus, which in some is possessed of little tenacity, and forms a very thin layer; whilst in other species, especially in such as have but slightly developed scales, it is of more consistency and furnishes a covering of considerable thickness, as for instance in the Tench and Eel. This fluid is secreted by a muciparous canal, which extends along the whole length of the body and ramifies extensively in the bones of the head. The fluid which it secretes, which is very viscid and difficult to mix with water, exudes at the surface through a number of orifices which are visible upon the cranium, upon the bones of the face, along the jaws, upon the preoperculum, and likewise through the series of tubes which perforate the scales along the lateral line. From these sources it is distributed all over the surface of

* Histoire de l'Academie Francoise, 1716 and 1718.

† This substance, argentine, under the name of "essence de l'orient," was extensively employed in the time of Reaumur for the manufacture of artificial pearls, and was on that account an exceedingly costly article.

the fish, as may easily be proved by drying it with a napkin, after which operation it soon becomes again covered with mucus, which issues from the openings of these pores.

In the Tunny (*Scomber thynnus*) there runs beneath the skin, following the entire length of the lateral line, an organ of a redder colour than the rest of the flesh, from which the little tubes forming the lateral line proceed, each tube receiving a nervous filament from the great lateral nerve. On raising the integument over this glandular organ a large vessel is seen, which, besides giving off arteries to the neighbouring muscles, furnishes an infinite number of branches to the glandular mass, beneath which, at nearly an inch from the surface, runs the lateral branch of the eighth pair of nerves, which in most other Fishes is situated immediately beneath the skin. It is in the Raidæ or Skates, however, that this system of vessels is most largely developed. In these broad-bodied fishes there is found upon the ventral aspect of the body a large canal which surrounds the prominent muzzle, forming very regular angles and windings, distributes its secretion by three or four branches on each side, and then winds upwards to terminate by different openings. There is, moreover, on each side at the external angle of the branchiæ a kind of sac which is round and of a whitish colour, which receives a large branch from the fifth pair of nerves, from which proceed a number of long simple vessels which run in radiating fasciculi in four or five different directions, and open at remote points on the surface of the body.

In Sharks the entire substance of the snout is made up of a dense cellulosity filled with a mucilaginous fluid, in which are imbedded fasciculi of tubes that open upon the surface of the skin by wide orifices. Besides these there are large vessels of similar character, one of which runs along the whole length of the animal on each side. Innumerable muciparous follicles contribute likewise to lubricate the skin, more especially in the vicinity of the snout.

By far the greater number of genera in the class before us are covered with imbricated scales, which overlap each other like the tiles of a house; the external and visible portion of these scales is covered with a thin layer of dermis, which soon dries on exposure to the air; their internal or concealed part is lodged in a cavity which is a kind of sacculus hollowed out in the dermis itself, or formed by one of its replications—an arrangement which at first sight appears very different from what exists in Lizards and Serpents, in which what is called a scale is only a production of the cutis covered by the epidermis, that on the outer surface assumes a greater consistency and thickness; but in the genus Scienus we have an intermediate arrangement between the imbricated scales of Fishes and what is met with in the scaly Reptilia. In the genus above mentioned the folds of the dermis are occupied by a calcareous plate, constituting a true scale easily separable from the cutis which envelopes it. We have only therefore to suppose the texture of this layer of cutis to be thinner and more delicate, and we arrive at once at the scale of a fish, which seems in a fossa excavated in the cutis. In Fishes the scales thus implanted in the true skin were supposed by Cuvier to have no vascular connection with it, but to originate like a shell in the mantle of a mollusk by the gradual deposition of consecutive layers deposited from the dermis; and all their varieties of surface, their different sculpture, the ridges or spines with which they are sometimes armed, and which frequently render them very beautiful objects for the microscope, were generally thought to have a similar origin.

Dr. Mandl* appears to have been the first who, by a microscopic examination of the intimate structure of the tissues which enter into the composition of the scales of Fishes, arrived at just conclusions relative to the mode of their formation, and proved that, so far from being mere exudations of corneous matter, they are produced, like the teeth and osseous tissue, by a true internal growth and nutrition.

The following is an abstract of the result of Dr. Mandl's researches upon this interesting subject, in which he satisfactorily proves that the scales of Fishes consist of two layers, of which the inferior exhibits a structure analogous to that of fibro-cartilage, whilst the superior resembles corpuscular cartilage, and is evidently formed by the developement of primitive cells.

Taking a well-developed scale, as that of a Carp, for an example, it is easy to perceive that its surface is marked with longitudinal lines arising from a common centre, and running towards the periphery of the scale, the number of which it is generally very easy to determine. The place towards which these lines converge is a space of variable dimensions, called by Dr. Mandl the *focus*. Between the longitudinal lines are seen, running parallel to the circumference of the scale, a very considerable number of concentric lines, which are crossed by the longitudinal ones at right angles; these are named "*cellular lines*," because they owe their origin to the developement of cells. Besides the parts above mentioned, many kinds of scales exhibit upon their surface, and upon one of their edges, spines of different forms, called by Dr. Mandl the *teeth* of the scale, a name which he founds upon the mode of developement of these appendages. Around the longitudinal and transverse lines, more especially near the point where the former converge towards the "*focus*," are numerous yellowish corpuscles of an elliptical shape, named the corpuscles of the scale.

Lastly, if the upper layer of the scale be raised or torn, an inferior stratum is displayed, of a fibrous character. These different structures he then proceeds to describe seriatim.

1. The *longitudinal lines*, which, arising from the *focus* of the scale, run towards its periphery, play an important part in the anatomy of the tissue we are examining, and when highly magnified are found to be so many canals exhibiting in the scales of different species

* Recherches sur la Structure interne des Ecailles des Poissons. Par le Dr. L. Mandl. Ann. des Sc. Nat. tom. xi.

every degree of formation from a simple furrow to a perfectly enclosed tube.

The broad scales or plates which form the armour of the Syngnathidæ are traversed by similar canals enclosed on all sides, which, although separate at the margins, anastomose freely towards the middle of the scale.

The longitudinal lines in all their forms constitute a series of hollow tubes that must be regarded as true canals. These canals traverse the scale in a longitudinal direction converging towards a focus, which, as will be shown hereafter, is a centre of nutrition, so that most probably these tubes perform the functions of nutritive vessels.

2. The *cellular lines*, supposed by preceding writers to be merely lines of growth analogous to those observable upon the exterior of a bivalve shell, attentive examination shews to owe their arrangement to a very different cause, originating in the developement of primitive cells, which are developed in the superficial stratum of the scale and gradually assume an elongated form, become filled with corneous matter, and ultimately arrange themselves in concentric lines of greater or less breadth, which only indicate by their uneven edges their original nature.

3. The *corpuscles* seen in scales are precisely similar in their appearance to those met with in bone and cartilage, and are obviously of the same nature. They are distributed in the basis membrane, which seems to be an amorphous tissue resembling that in which the corpuscles of bone are deposited, and which forms the superficial stratum of the scale.

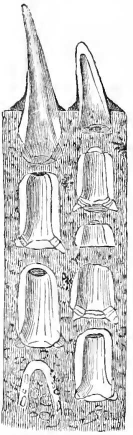
4. The *fibrous layer*.—On scraping off with a penknife the external surface of the scale, the cellular lines and the corpuscles with their basal membrane are removed, and the deep-seated stratum of the scale becomes visible, which is then seen to consist of fibrous lamellæ composed of fibres that cross each other at regular angles, giving to this tissue the appearance of fibro-cartilage. This layer is thickest near the focus of the scale, and become gradually thinner towards the edges.

5. The *focus* is the space towards which the longitudinal lines converge, but is not always situated in the centre of the scale; it is occupied by very large pale corpuscles and by interrupted circular lines; such at least is its appearance in the scales of Acanthopterygenous Fishes, but in the Malacopterygii, and more especially in those species which have membranous scales, it presents nothing but a smooth circumscribed surface without corpuscles or interrupted laminæ, and is then generally surrounded by the concentric cellular lines.

6. *The teeth of the scales*.—The growth of the spines and other appendages seen upon the outer surface and posterior margin of many forms of scales, more especially in those named *ctenoid* by Agassiz, is a subject of very considerable interest, and to the old physiologists, who believed all scales formed by mere exudation, must have been quite unintelligible. The production of these spines is in fact, according to the researches of Dr. Mandl, in every respect similar to the growth of teeth, each being enclosed in a distinct capsule and developed in the following manner, as exemplified by the growth of a scale of *Corvina nigra*, one of the Scienidæ.

The posterior margin of one of these scales is occupied by conical appendages, represented in a highly magnified condition in *fig*. 508. Each of the oblong processes here depicted is seen to be enclosed in an envelope, from which, however, it is entirely separate, as is proved by the fact that when the capsule is ruptured the enclosed spine can be removed from it with the utmost facility. Examined in detail, every one of these spines exhibits an organization and mode of growth precisely similar to that of a tooth, being formed in its capsule exactly in a similar manner. The germ begins gradually to develope itself; it acquires roots, and becomes distinctly composed of different layers, so that these spines may with propriety be called the teeth of the scales, in allusion to the mode of their developement. The marginal teeth are most developed, and those nearest the focus least so. Thus in the figure the two superior teeth are seen enclosed in their capsules, their bases thick and well formed, and the whole surface of the tooth smooth and continuous. In the two next teeth below, the developement is much less advanced; the extremities are truncated, the external layer of the tooth does not entirely cover it, but the roots are visible. Still lower down the teeth of the scale become more and more imperfect, until the lowest are scarcely at all developed, and are barely distinguishable among the surrounding corpuscles.

Fig. 508.



A small portion of the scale of Corvina nigra, highly magnified, shewing the progressive developement of the teeth upon its surface. (After Mandl.)

In other families with denticulated scales the growth of these appendages is precisely similar, as in the Gobioides, Percoides, Pleuronectidæ, &c.

From the above observations it becomes evident that the scales of Fishes can no longer be regarded as mere productions of secretion from the skin, but must be considered as possessing an inherent power of nutrition and a true growth. The denticles which exist upon many of these scales offer by their successive developement a striking proof of this important fact; while the canals whereby they are traversed, and the corpuscles belonging to their structure, plainly intimate that their mode of developement is similar to what exists in the teeth and in the osseous system.

The chemical composition of the scales of Fishes, moreover, very nearly approximates that of their teeth and bones, as will be evident from the following analysis made by M. Chevreul of the scales of a Lepidosteus, of a Chetodon, and of the Perca labrax, after they had been thoroughly dried by exposure during six weeks to a dry atmosphere. In drying, the scales of Lepidosteus lost 11.75 per cent., of Chetodon 13 per cent., and those of the Perca labrax 16 per cent.

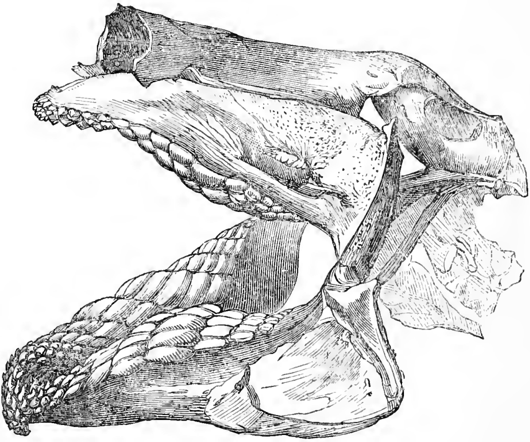
In a preceding article (see OSSEOUS SYSTEM, Comp. Anat.) we have endeavoured to shew that the scales which invest the exterior of the body constituting the exoskeleton of Fishes, by progressive modifications in their size, texture, and arrangement, are converted into very various organs, namely, the apparently osseous plates that cover *Lepidosteus* and *Ostracion*, the formidable prickles that stud the external surface of the *Diodons*, the opercular flaps of the Sturgeon, and even those of the osseous Fishes; the spines of *Gasterosteus*, and those which in *Silurus*, *Balistes*, and *Lophius*, were likewise proved to belong to the epidermic or tegumentary system; lastly, the fin-rays and interspinous bones of the vertical fins were found to be derivations from the exoskeleton, instead of being, as they have long been considered, parts appertaining to the endoskeleton or true osseous system.

The dental organs of vertebrate animals have very naturally been regarded by the old anatomists who confined their osteological researches to the investigation of the human skeleton, as forming a part of the bony framework of the body, notwithstanding that the teeth in every particular of their economy were confessedly very different from any other pieces of the skeleton.

Any one who with a little care examines the dental apparatus of Fishes will, however, speedily be convinced that the *teeth* in common with the epidermic structures above enumerated are all of cuticular origin, their connection with the real osseous skeleton, by their roots becoming consolidated with certain bones of the mouth or implanted into the jaws, being by no means an essential or even constant circumstance.

Every one knows that the skin covering the body of the Skate or Thornback is thickly studded with calcareous spines, some of microscopic size, but others of considerable dimensions. On tracing these cuticular spines towards the mouth they are found, as they pass over the manducatory surfaces of the upper and lower jaws, to become suddenly very much increased in size, and are arranged with such regularity that they constitute a very formidable set of dental organs, consisting of ten or a dozen rows of sharp teeth, which answer every purpose connected with the seizing and swallowing of food. These teeth, however, or scales, for such they indubitably are, have no connection with the jaws that support them except through the intermedium of the cutis or mucous membrane covering the mouth, from which they are developed, and are continually in these Plagiostome genera in progress of formation behind as they are worn away in front, their developement being accomplished in the following manner.* A series of minute and closely aggregated papilliform matrices or pulps rise in succession from the mucous membrane behind the teeth already formed, which gradually become ossified by the deposition of calcareous salts in the peripheral cells and radiating tubes of which the pulp consists.

Fig. 509.



Skull and jaws of Port Jackson Shark (Cestracion Philippii), shewing the forms and arrangement of the teeth.

* Owen, Odontography, 4to. 1840.

In *Mylobates*, a kind of Ray, in which the teeth are most perfectly adapted for crushing and bruising food, the arrangement of the dental apparatus is very curious. In this fish the teeth form broad plates, which are of hexagonal shape, and so closely fitted together by their edges that they form a complete tesselated pavement.

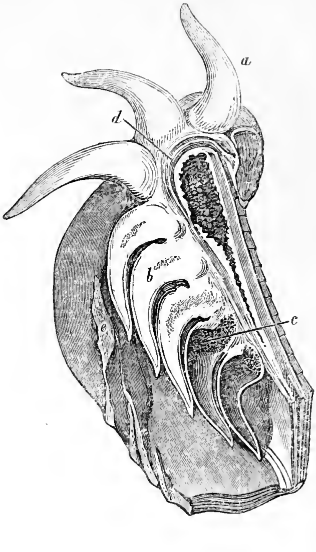
In the *Cestracion Philippii*, or Port Jackson Shark, both the above descriptions of teeth are found united in the same jaws, the anterior resembling the sharp teeth of the common Rays, while the posterior are broad and disposed like the paving-stones in a street (*fig.* 509). The Mylobates affords, moreover, an additional proof of a very convincing description that the teeth of Fishes are developed from the lining membrane of the mouth quite independently of the jaws, seeing that here there is a row developed from the mesial line of the jaws, precisely over the symphysis—a circumstance never observable in the higher animals, where the jaws and teeth are brought into closer relation with each other.

The teeth of the Squaloid Fishes or true Sharks are renewed by a very similar mode of growth. In these redoubtable monsters of the deep the teeth consist of numerous rows of broad and trenchant laminæ, the anterior row of which (*fig.* 510, *a*) stands up perpendicularly from the jaws ready for use, while the succeeding layers are recumbent, being covered over by a fold of the mucous lining of the mouth. These teeth, like those of the Rays, are perpetually renovated, new and sharp rows being constantly ready behind to replace the old and worn ones in front as soon as the latter fall out or become useless.

The situation of these teeth and their mode of growth is represented in the annexed figure. Their only connection with the cartilaginous jaw is evidently through the medium of the interposed fibro-mucous layer (*d*), which, as it slowly advances forward, carries the teeth with it, and thus brings the successive rows progressively into use. In the Sharks there is no distinct pulp, the dense exterior layer of the tooth being formed by the calcification of the "membrana propria" of the pulp, so that when divided they are found to be permanently hollow, as represented in the figure (*c*).

In the Cyclostomatous Fishes the teeth are still more evidently mere cuticular appendages, seeing that in their case there are no bony jaws to which they can be affixed. In the *Myxine Glutinosa*, the Hag-fish, one of the most humbly organized but at the same time the most formidable of the finny tribes, this is extremely evident. The Myxine is generally found buried in the substance of some large fish which it has attacked, and by means of the tremendous apparatus we are about to describe succeeds in penetrating, tearing, and devouring the soft parts of its unfortunate victim as it pioneers its way into its interior. In order to effect this these fishes are furnished with a single sharp and recurved fang attached to the centre of the roof of their mouth and fixed to the cartilages of the cranium by strong

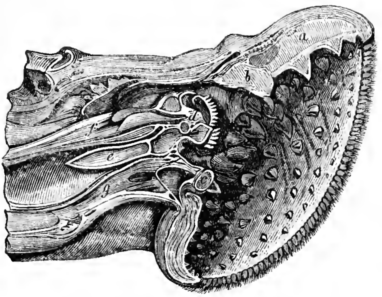
Fig. 510.



fibrous bands. Inferiorly the surface of the tongue is covered with four rows of sharp horny blades, two rows being placed on each side, the whole apparatus being susceptible of being advanced and retracted by means of strong muscles. It is not difficult, therefore, to imagine the efficiency of a dental apparatus such as this in enabling the Myxine to accomplish its murderous purpose.

The Lampreys, likewise, whose parasitic habits are not very dissimilar from those of the *Myxine*, have a very singular dental apparatus, which is quite distinct from the cartilaginous skeleton, and evidently purely composed of epidermic structures. The teeth of the Lamprey are composed of horny plates or tubercles of different forms, which are disposed with great regularity over the whole surface of the sucker-shaped mouth. Each of these horny teeth is supported upon and secreted by a pulp derived from the mucous membrane of the mouth, much in the same manner as other corneous epidermic structures, and from their disposition will evidently secure a deadly hold of any victim seized upon. Besides these labial teeth there is one fixed to the roof of the mouth which is obviously analogous to the solitary palatine fang of Myxine last described. This (*fig.* 511, *b*) is composed of two horny cones attached by fibrous ligaments to the palatine cartilages in the roof of the mouth. The tongue (*d*), which, like that of the Myxine, is here very moveable and capable of being retracted and protruded by means of strong muscles, is likewise armed with serrated teeth, with which, as with a rasp, the Lamprey tears through the flesh of its prey.

Fig. 511.



Seeing, therefore, that the teeth of Fishes are derivations from pulps formed by the mucous lining of the mouth, it can be a matter of small astonishment to find that they can be developed in any part of the oral cavity where the necessities of a given species may require their presence, without relation to the jaws, with which alone they are connected in the highest races of Vertebrata and in the human subject.

Accordingly in the class under consideration teeth are found attached to any or all of the following parts of the mouth and of the pharynx, viz. to the superior and inferior maxillæ, to the intermaxillary bones, to the palate bones, to the vomer, to the tongue, to the branchial arches, and to the superior and inferior pharyngeal bones. The ichthyologist is therefore compelled to designate the different parts of the dental system according to the bones or other structures whereon they are situated, and distinguishes intermaxillary teeth, maxillary teeth, mandibular teeth, vomerian teeth, palatine teeth, pterygoid teeth, lingual teeth, branchial teeth, superior pharyngeal teeth, and inferior pharyngeal teeth, all of which may sometimes be coexistent, rendering the teeth of Fishes prodigiously numerous. As relates to their form the dental organs offer a far greater number of varieties than those of other vertebrate animals. Sometimes they are so minute as only to be perceptible by the rough or scabrous surface which the parts of the mouth to which they are attached present. If of larger size, they present the appearance of a file or rasp *(dents en rape)*, or they may have the shape of small cones or hooks thickly scattered over the parietes of the mouth. Sometimes they are so fine and slender as to resemble the pile of velvet *(dents en velours)*, or elongated, having the appearance of fine bristles. In *Citharina* these bristle-shaped teeth are bifurcated towards their free extremities, or they may terminate in three diverging points, as in the anterior teeth of the genus *Platax*. Or the elongated cone may be compressed into a slender trenchant plate, and this may be pointed, recurved, or even barbed like a fish-hook, as is the case in *Trichiurus* and some other Scomberoid Fishes; or it may be bent upon itself like a tenter hook, as in *Pemelepterus* and *Goniodontes*. Sometimes the dental cones present a thickened base, giving them the appearance of the laniary teeth of carnivorous quadrupeds, as is the case with the large teeth of the *Pike;* or they may be flattened into broad plates of hemispherical or other shapes, constituting a crushing apparatus adapted to bruise the food.

A thin lamella, slightly concave like a finger nail, is the singular form of the tooth of an extinct species of cartilaginous fish named by Professor Owen *Petalodus*.* Sometimes each tooth presents a flattened incisor crown deeply notched in the middle of the cutting edge, as in *Sargus unmaculatus*. Sometimes there is a double notch, rendering the margin of the tooth trilobate, as in *Aplodactylus;* or it may be divided into five lobes by a double notch on each side of the central and largest lobe, as in *Boops*.

In the great Barracuda pike *(Sphyræna)* the crown of both the large and small lamelliform teeth is prolonged into a sharp point, closely resembling a lancet. A similarly shaped piercing and cutting tooth is in many of the Sharks furnished with one or more accessory cusps at its base, and the cutting margins of the tooth are frequently notched, serrated, or crenated. Prismatic teeth with three sides are fixed to the jaws of *Myletes;* and in some instances, as in Scarus, they assume the shape of four-sided prisms.

The teeth of Fishes† present greater diversity in their mode as well as in their place of attachment than is observable in any other class of animals. In a few instances they are implanted in sockets, to which they are attached only by the surrounding soft parts, as, *e. g.* the rostral teeth of the Saw-fish (Pristis). Some have their hollow base supported, like the claws of the feline tribes, upon bony prominences which rise from the base of the socket; the incisors of the File-fish *(Balistes)* afford this curious example of a double gomphosis, the jaw and the tooth reciprocally receiving and being received by each other.

The teeth of *Sphyræna*, *Acanthurus*, *Dictyodus*, &c. are examples of the ordinary implantation in sockets with the addition of a slight anchylosis between the base of the fully formed tooth and the parietes of the alveolar cavity. But by far the most common mode of attachment of fully formed teeth is by a continuous ossification between the dental substance and the jaw, the transition being gradual from the dental to the osseous tissue. The tooth prior to its anchylosis is connected by ligamentous substance, either to a plain surface, an eminence, or a shallow depression in the bone.

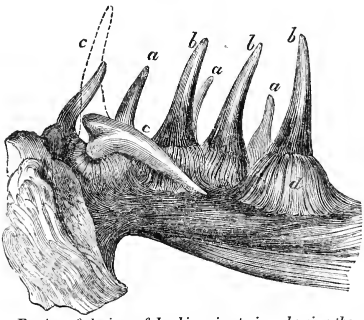
Sometimes not the end, but one side of the base of the tooth is attached by anchylosis to the alveolar border of the jaw; it might be supposed that in this case the crowns of the

* Owen, Odontography, p. 2.
† Owen, loc. cit.

teeth in both jaws would project forwards instead of being opposed to one another, and such, in fact, must have been their position were it not that, as in *Pimelepterus*, the teeth are bent at nearly a right angle with their base. In the *Scarus*, and likewise in the marginal teeth of the *Diodon*, where these organs are straight and attached horizontally to the margin of the jaws, their sides instead of their crowns are actually opposed to each other.

In the Cod-fish, Wolf-fish, and some other species, in proportion as the ossification of the tooth advances towards its base and along the connecting ligamentous substance, the subjacent portion of the jaw-bone receives

Fig. 512.



Portion of the jaw of Lophius piscatorius, showing the ligamentous attachment of the teeth.

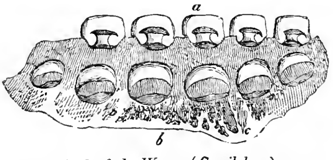
a, a, a, anterior teeth; b, b, b, posterior teeth in their erect position; c, one of these teeth laid flat towards the interior of the mouth, the dotted lines indicating its condition when erect. (After Owen.)

a stimulus and developes a process corresponding in size and form with the solidified basis of the tooth. In this case the inequalities of the opposed surfaces of the tooth and maxillary dental process fit into each other, and for some time they are firmly attached together by a thin layer of ligamentous substance; but, in general, anchylosis takes place to a greater or less extent before the tooth is shed. The small anterior maxillary teeth of the Angler (*Lophius*) are thus attached to the jaw, but the large posterior ones remain always moveably connected by highly elastic glistening ligaments, which pass from the inner side of the base of the tooth to the jaw-bone (*fig.* 512, *d*). These ligaments do not permit the tooth to be bent outwards beyond the vertical position, when the hollow base of the tooth rests upon a circular ridge growing from the alveolar margin of the jaw; but the ligaments yield to pressure upon the tooth in the contrary direction, and its point may thus be directed towards the back of the mouth; the instant, however, that the pressure is remitted, the tooth flies back, as by the action of a spring, into its former position. The deglutition of the prey of this voracious fish is thus facilitated and its escape prevented.

The teeth of the Wolf-fish, *Anarrhicus*, are extremely remarkable. They do not adhere immediately to the jaw or to the palate bone, but are attached to conical or hemispherical osseous epiphyses, which are fixed to these bones by a kind of suture, and are easily detached at certain periods. The base of each of these epiphyses is surrounded with a row of small foramina, doubtless intended for the admission of vessels, and mark the line of separation. On the summit of these cones the true teeth, formed as usual of dentine and enamel, are attached.

" If," says Professor Owen, in the valuable treatise from which we have extracted the preceding paragraphs, " the engineer would study the model of a dome of unusual strength and so supported as to relieve from its pressure the floor of a vaulted chamber beneath, let him make a vertical section of one of the pharyngeal teeth of the *Wrasse* (*fig.* 513). The base of this tooth is slightly contracted and is implanted in a shallow circular cavity, the rounded margin of which is adapted to a circular groove in the contracted part of the base. The margin of the tooth which thus immediately transmits the pressure to the bone is strengthened by an inwardly projecting convex ridge. The masonry of this internal buttress and of the dome itself is composed of hollow columns, every one of which is placed so as best to resist or to transmit in a due direction the superincumbent pressure." The use of this beautiful piece of animal mechanics is to keep the delicate successional pulp which is lodged beneath the vault of the arched tooth, from being injured by pressure during the action of these powerful crushing teeth.

Fig. 513.



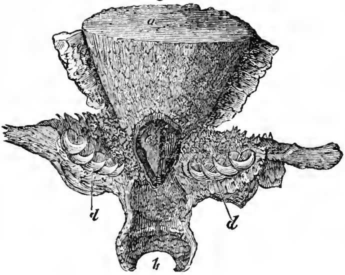
Teeth of the Wrasse (Crenilabrus).
Portion of the pharyngeal bone of the Wrasse.

a, structure of arched teeth; b, successional teeth; c, bone.

In *Rhizodus*, a large extinct species of Sauroid fish, the broad base of the tooth is divided into a number of long and slender cylindrical processes, which are implanted like piles in the coarse osseous substance of the jaw. They diverge as they descend, and their extremities bend and subdivide like the roots of a tree and are ultimately lost in the bony tissue. This mode of attachment of a tooth is perhaps the most complicated met with in the animal kingdom.

In order to complete our remarks concerning the teeth of Fishes it only remains to notice a few examples in which the dentition is peculiar, namely, in the Cyprinidæ, the Scari, the Diodons, and the Tetradons.

Fig. 514.

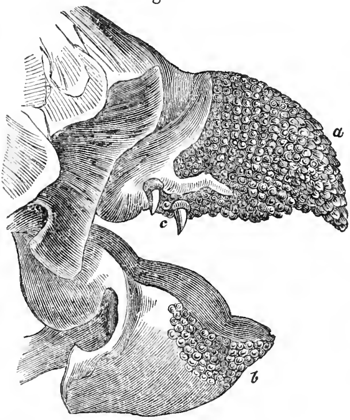


Teeth of the Tench.

a, roof of the mouth; *b,* the œsophagus; *c,* dental projection from basilar bone; *d, d,* pharyngeal teeth. (After Owen.)

In the *Cyprinidæ*, or Carp-genus, the bones composing the superior and inferior maxillæ are completely edentulous, but to make up for this deficiency the pharyngeal bones are armed with a remarkably powerful dental apparatus of very singular character. Each of the inferior pharyngeal bones, which are exceedingly strong and form a kind of osseous framework at the commencement of the œsophagus, supports four or five large teeth of great strength. These are opposed to a single dental piece of stony hardness and laminated structure, which is fixed upon a dilated projection from the basilar bone of the cranium (*fig.* 514), and thus forms a kind of anvil upon which the bruising pharyngeal teeth play, and thus crush and triturate whatever food passes into the œsophagus.

Fig. 515.

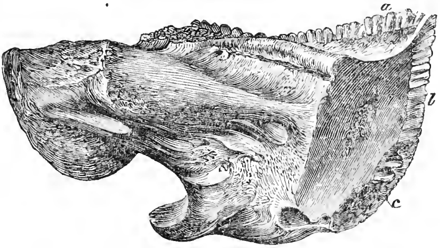


Beak of Parrot-fish (Scarus muricatus).

a, upper mandible, the exterior of which is completely encased in teeth; *b,* lower mandible partially so, the inferior teeth not having as yet protruded; *c,* lateral fangs. (After Owen.)

In the Scari, which have to feed upon the numerous corallines that clothe the rocks at the bottom of the ocean, the dental apparatus given to protect their jaws from injury while biting such hard substances is very remarkable. These Fishes have their jaws, which resemble the beak of a parrot (whence they receive their usual appellation "Parrot-fishes,") covered externally with a kind of pavement of teeth answering the same purpose as the horny investment of the mandibles of the bird. The teeth that form this pavement are perpetually in progress of developement towards the base of the jaw, whence they advance forwards, when completed, to replace those which become

Fig. 516.



Section of the jaw of the Parrot-fish, shewing the progress of dentition.

c, teeth still enclosed in the jaw; *l,* do. with their extremities protruded so as to form an external pavement. (After Owen.)

worn away in front by the constant attrition to which they are subjected.

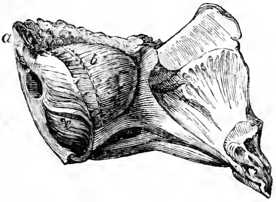
In the annexed figure (*fig.* 515) the external appearance of these singularly disposed teeth is well represented, while in the vertical section (*fig.* 516) the mode of their implantation into the anterior surface of the jaw is delineated. All these teeth were originally developed in a common alveolar cavity (516, *c*) situated in the substance of the jaw. The outer* wall of this cavity is much weaker than the dense and compact inner wall, and moreover it becomes thinner as it approaches the margin of the jaws and disappears (*fig.* 516, *l,*) at different distances in different species of Scari before it reaches that margin. Where it exists at the base of the jaws it is sometimes, as in *Scarus muricatus* represented in the figure, perforated by numerous small foramina, through which foramina in the recent fish processes of the external periosteum are continued to the analogous membrane lining the dentigerous cavity and forming the capsule of each denticle. These processes are analogous to the gubernacula of the second series of teeth in the Mammalia, and like them serve to conduct the new teeth to the exterior of the jaw. The growing denticles (516, *l,*) be-

* Owen, Odontography, page 115.

come elongated by the addition of successively calcified portions of their pulp to their basal or posterior extremities; the opposite end exerts a proportional pressure against the circumference of the foramen, and causing its absorption begins to protrude. The tuberculate crown of the denticle is exposed about the time when its sides become anchylosed to those of the previously protruded row. Thus, from the close apposition of the protruding denticles, the whole of the outer parietes of their common alveolar cavity subjected to the stimulus of their pressure is finally removed, and is replaced by the pavement of mutually anchylosed teeth (*fig.* 515, *a*).

In the *Diodons* and *Tetradons* the structure of the teeth is equally peculiar, but of a very different character from what has been described above. In the former genus each jaw is furnished with a double compound tooth adapted to crush and bruise the food, the structure of which at once reminds the anatomist of the molar teeth of the elephant. Each tooth (*fig.* 517) consists of numerous laminæ superimposed upon each other, the upper ones being the oldest and most worn, while the lower ones are the largest and most recently formed. In consequence of this arrangement

Fig. 517.



Section of the lower jaw of the Globe-fish (Diodon), shewing the structure of its teeth.

a, circumference of jaw; *b*, grinding surface of tooth within the mouth. (After Owen.)

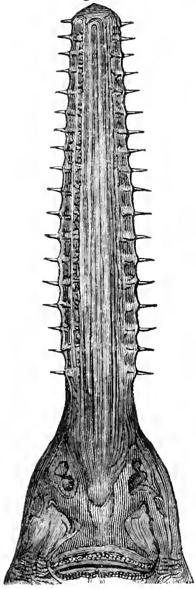
the exposed surface of the tooth that projects into the mouth (*b*) presents a grooved appearance, being formed of the edges of the contiguous lamellæ that are situated towards the upper part of the tooth. As these superior laminæ are worn away, it is evident that they are continually replaced by the advancement upwards of the inferior plates, so that the tooth is kept constantly efficient for service. The circumference of the jaw (*a*) is formed of superimposed plates which grow from below in a precisely similar manner; but between these and the posterior laminated tooth a very different structure is interposed, which is revealed by the microscope to consist of a series of narrow flattened denticles lying horizontally and at right angles to the anterior surface of the jaw. These denticles are developed in a cavity between the outer and inner walls of the jaw, the floor of which is formed by a thin cribriform osseous plate separating the cavity containing the teeth from the wide vascular canal which runs in the substance of the jaw. In the *Tetradons* a somewhat similar structure of the dental organs is met with.

The rostral teeth of the Saw-fishes, *Pristis*, are quite unique among the whole race of Fishes from the singular position which they occupy, as will be perceived by the following account of this strange apparatus extracted from Professor Owen's elaborate treatise.

"The maxillary teeth of the Saw-fish, which is an active and predatory Shark, are, notwithstanding its habits, extremely small, simple, obtuse, and wholly inadequate to destroy and secure the prey requisite for its subsistence. But this seemingly imperfect armature of the mouth is compensated for by the developement from the anterior part of the head of a very singular and formidable weapon provided with strong lateral teeth, and which from its resemblance to a saw has given rise to the vernacular of 'Saw-fish,' applied to the present species of Shark."

In most of the Plagiostomes, but especially in the group of Squaloids, a conical projection or cutwater is continued from the fore-part of the head, and its framework is composed of peculiar and superadded cartilages articulated to the anterior extremities of the frontal, nasal, and vomerine bones. These rostral cartilages in the Saw-fish (*Pristis antiquorum*) are blended into a horizontally flattened plate, which is produced to a length equalling one-third that of the entire fish: this process is more completely ossified than any other part

Fig. 518.



Rostrum of Saw-fish (Pristis antiquorum), shewing the marginal teeth.

of the skeleton, and a series of deep alveoli is excavated in each of its lateral margins (*fig.* 518).

The teeth which are lodged in these sockets are elongated, compressed in the same plane as that of the body of the saw, and their edges converge to a sharp point, which is situated a little behind the axis of the tooth. Each rostral tooth is solid, its base being slightly concave and porous like the section of a cane, but the pores are finer and more numerous. The walls of the socket are formed by ossification of the rostral cartilages to an adequate extent; but as unnecessary weight under any circumstances, but especially at the fore-end of the fish, would be a cumbrous impediment to its motions, the spaces intervening between the sockets are hollow and filled with a gelatinous medulla. A large vascular canal traversed by branches of the facial artery and of the second division of the fifth pair of nerves enclosed in a cellular gelatinous tissue, runs parallel with the axis of the saw along the back part of the alveoli, and supplies the materials for the increase of the teeth, which are not shed and renewed like the maxillary teeth, but grow with the growth of the body by constant addition of fresh pulp-material progressively ossified at their base.

Œsophagus.—Owing to the extreme shortness of the passage between the cavity of the mouth and the stomach, the length of this tube is extremely limited in the whole race of Fishes; nevertheless, occasionally its boundaries are well marked, and its structure sufficiently distinct from that of the alimentary canal to entitle this part of the digestive apparatus to a brief notice. Its walls are generally strong and muscular for the purpose of passing the food into the stomachal cavity, but more especially so in those voracious Fishes which swallow dense and indigestible shells of various kinds, or that are subject to have their stomachs loaded with the hard bones of digested fishes, all which materials are in such instances regurgitated and thrown out of the mouth much after the manner of the "castings" of the Hawk or Owl among birds of prey. In a few races, however, the œsophagus exhibits peculiarities of structure that are remarkable. Thus in the *Torpedo* and others of the Ray genus, there is a very thick layer of a soft and semi-gelatinous substance interposed between the lining membrane and the muscular coat, the use of which it is by no means easy to conjecture. In the Sturgeon the mucous membrane of the gullet is prolonged into transverse valvular folds, analogous in their nature to the conical processes found in that of the *Turtle*. But the most striking example of a valvular apparatus situated in this part of the digestive tube is met with in the Sharks (*fig.* 519), in which race of Fishes the termination of the œsophagus is indicated by a great number of long fleshy stems, which divide and subdivide into very numerous branches, and thus form a dense and prominent fringe hanging loosely downwards towards the stomach, in such a way as to allow anything swallowed to pass freely in that direction, but by the interlacement of the fringes effectually preventing anything from returning towards the mouth. This structure is most conspicuously seen in the great Shark (*Squalus maximus*), in which species, owing to the comparative smallness of the teeth which arm the jaws, it is extremely probable that many Fishes are swallowed alive and might retain their vitality sufficiently long to struggle back again out of the stomach of their devourer, did not this strange gate effectually bar their progress.

Stomach.—This viscus is, in the generality of species, a musculo-membranous bag of very simple structure and of variable shape in different genera. Sometimes, however, its muscular walls are sufficiently strong to perform to a certain extent the functions of a gizzard: this seems to be the case, for example, in the *Gillaroo Trout* (*Salmo fario*), and to a far more remarkable extent in the Mullets (*Mugil*), in which the œsophagus terminates inferiorly in a deep cul-de-sac that serves the purpose of a crop. The muscular stomach or gizzard opens from one side of this œsophageal bag, to which it is attached at right angles. Its shape is pyriform, the narrow end being directed towards the intestine, and its muscular walls nearly half an inch thick. Internally it presents numerous longitudinal folds, all covered with a thick cuticular lining, and evidently the whole apparatus is very analogous to the true gizzard of a granivorous bird. It was John Hunter's opinion that neither of these can be justly regarded as gizzards, since they want the most essential characters, namely, a power and motion fit for grinding, and a horny cuticular lining. According to Professor Owen, however, the latter structure exists in the gizzard of the Mullet as a distinct layer of rough and easily separable cuticle. The stomach of the Gillaroo or Gizzard-trout is certainly, as described by Hunter, more globular in its shape than that of most Fish, and endued with sufficient strength to break the shells of small shell-fish, which is probably accomplished by having more than one in the stomach at a time, and also by taking pretty large and smooth stones into the stomach, which will answer the purpose of breaking, but not so well that of grinding; nor will they hurt the stomach, as they are smooth when swallowed; but this stomach can scarcely possess any power of grinding, as the whole cavity is lined with a fine villous coat, the internal surface of which appears everywhere to be digestive. The common stream-trout, which only differs from the "Gillaroo" in having the walls of its stomach not so thick by two-thirds as the other variety, likewise swallows smooth round stones wherewith to crush the shell-fish which it occasionally devours.

Intestinal canal.—The intestines of Fishes present as many variations as regards their relative length when compared with that of the body, as do those of any of the higher Vertebrata, but their general arrangement is of a much more simple character. In the Flying-fish (*Exocetus*), indeed, it presents the simplest possible form, being merely a straight tube passing directly from the stomach to the anus. In the Mullets (*Mugil*), on the contrary, the intestine is of great length and is very curiously folded, being intervolved with the folds of the liver so as to form a mass of triangular form moulded to the shape of the abdominal cavity, and affording an example of the longest and, in its disposition, the most complex intestinal canal of any of the class.

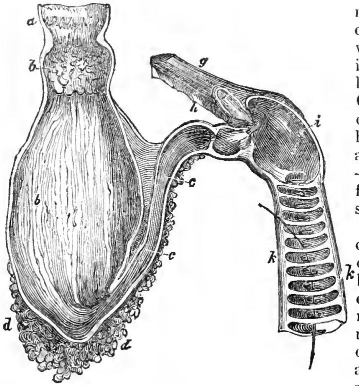
This arrangement, as Rathke very justly observes, is an obvious approximation to the disposition of the viscera most generally met with in molluscous animals, in which the folds of the intestine are prolonged into and almost buried among the folds of their very large liver.

In the *Electric Eel* (*Gymnotus electricus*) the disposition and termination of the intestinal tube is curious. First descending to the lower end of the stomach, it passes to the left side and ascends again as far as the œsophagus; it then winds downwards and backwards so as to encircle the stomach, and, lastly, advancing forwards along the ventral aspect of the abdomen, it terminates, as in the Cephalopoda, beneath the throat, in the immediate vicinity of the heart and root of the tongue.

No fish has anything like a colon or cœcum. The only distinction between small and large intestines is met with just at the termination of the alimentary tube, where it opens into a kind of cloacal cavity, usually called the *rectum*. At this point there is generally a prominent circular fold of the lining membrane constituting a kind of valve. In the Salmon several of these valvular zones succeed each other, giving to this part of the gut an appearance similar to that of the intestine of the Plagiostome cartilaginous Fishes immediately to be described.

In the Sharks and Rays, the Plagiostomes

Fig. 519.



Alimentary canal of Shark.

a, œsophagus; *b*, *b*, cavity of stomach, at the commencement of which are placed the valvular fringes mentioned in the text; *c*, passage leading to pylorus; *d*, spleen; *e*, pyloric cavity; *f*, dilated chamber; *g*, *h*, bile-ducts; *i*, orifice of pancreatic duct; *k*, *k*, valvular intestine.

just referred to, and also in the Sturgeon, the intestine presents a very remarkable structure. Externally it resembles a wide bag nearly similar in shape and size to the stomach itself, and so short and stunted that, without some special arrangement, obviously a sufficient surface would not be afforded for the absorption of the nutritious portions of the food. By the mechanism adopted, however, this is abundantly provided. Throughout the whole length of the gut the mucous membrane is arranged in deep spiral folds (*fig.* 519), which wind from end to end, only leaving a small orifice in the centre of each valvular projection, whereby the different compartments formed between the spiral lamina can communicate with each other, so that the digested food by this unusual arrangement is spread over a very great superficial area, and all the benefits of a long and convoluted intestinal tube are secured. Each fold of this extensive spiral valve contains between the layers of mucous membrane that compose it an elastic substance, whereby it is kept constantly spread out and restored to its original position when displaced by the passage of food through the central channel that permeates the whole series.

In the Sturgeons a similar valve exists, but its spiral folds are not so closely arranged: the intestine, moreover, is remarkable on account of the great thickness of its muscular and internal tunics, the latter of which presents a reticulated or honey-combed appearance, the larger meshes including irregular spaces, which are again subdivided into smaller cells. Slight vestiges of the spiral intestinal valve are visible even in the Lamprey.

Salivary glands.—From the circumstances under which Fishes swallow their food, the presence of any salivary apparatus is evidently uncalled for; no fish, therefore, possesses true salivary glands. Nevertheless, in the Cyprinidæ and some other races the whole palate is covered with a soft spongy substance, from which a kind of mucosity is discharged through imperceptible pores, which has been regarded by Rathke and others as a salivary organ: Cuvier, however, denies the glandular character of this substance, regarding it as a peculiar and highly sensible tissue destined to be the seat of a sense more or less analogous to that of taste, —a supposition that is rendered more probable from the great number of nerves that enter its substance.

Pancreas.—In the osseous Fishes no pancreas, such as that met with in the higher classes of vertebrate animals, exists; it is, however, represented by a variable number of cœcal appendages, which open into the duodenum in the vicinity of the pylorus. The lining membrane of these pyloric cœca is of a glandular character, and secretes an abundance of a thin glairy fluid analogous to the pancreatic secretion. The existence of the appendages in question is, however, by no means constant; thus in the *Labridæ*, the *Siluridæ*, the *Cyprinidæ*, and many members of the pike genus, they are altogether wanting. When present, moreover, their number varies very remarkably in different Fishes; thus, sometimes, as in the

Salmonidæ, they are extremely numerous, while in other races, the *Pleuronectidæ* for example, there are only two cœca attached to the pylorus. That the pyloric appendages are strictly analogous to the pancreas, exhibiting that gland in its simplest condition, such as it presents in the embryonic state of the higher animals, is proved by the gradual transition that may be traced from the condition in which they exist as above described, and the undoubted pancreatic gland met with in the more highly organized cartilaginous Fishes. Thus in the Cod-fish *(Gadus morrhua)* the pancreatic cœca unite together as they approach the duodenum, so as to communicate with that intestine by comparatively few orifices situated in the vicinity of the pylorus; and in the Sturgeons this coalescence of the cœcal tubes is still more conspicuous, for in that race of Fishes the pyloric appendages are very short, and so connected together by vessels and cellular membrane into a single mass, that they here present a precisely intermediate condition between the free cœca of the osseous Fishes and the conglomerate pancreas possessed by the Sharks and Rays.

In the plagiostome cartilaginous Fishes last named, the pancreas is in fact a true conglomerate gland, resembling that of Quadrupeds, and in the same manner pouring its secretion into the intestine through a single excretory duct, which runs obliquely for a considerable distance between the coats of the duodenum, and terminates in the vicinity of the *ductus choledochus*.

Liver.—The liver of Fishes is generally of very great relative size, and frequently contains in its tissue such an enormous quantity of oil, that this alone forms an important article of commerce. Its texture is exceedingly soft, and from the arrangement of the vessels in its interior sometimes exhibits a fibrous appearance. The lobes of which it consists are generally very numerous, but there is always a gall-bladder, from which the bile is poured into the intestines through a single duct, which terminates in the duodenum near the pylorus.

Spleen.—This viscus, which is peculiar to the Vertebrata, first makes its appearance as we trace the animal series upwards in the class under consideration. In Fishes it is of very variable size, but is always present. Its usual position is among the folds of the intestines, and its relations with the stomach are so different to what obtains in the mammiferous races, that its functions cannot be in any way influenced by pressure caused by the distension of that organ. In its supply of arterial blood, which is subsequently transmitted to the portal system, it differs in no essential particular from what occurs in the other vertebrate classes.

All the above viscera are lodged in the cavity of the abdomen, in which they are suspended by numerous irregular folds of peritoneum; the generative and urinary organs, as well as the swimming bladder hereafter to be described, being situated beneath the spine external to the peritoneal sac, the peritoneum only covering their anterior surfaces. In many Fishes the peritoneum does not form a closed bag, as is the case with the serous membranes in general, but on the contrary is penetrated by two large orifices situated in the vicinity of the anus, through which the peritoneal membrane becomes continuous with the external integument, and in this respect assimilates a mucous surface. Such is the case in the Sturgeons, Lampreys, Salmons, Sharks, and Rays: in the two last genera, indeed, the connection is still further extended by two orifices, through which the peritoneal bag communicates with the cavity of the pericardium. The mesentery is in Fishes very incomplete, consisting merely of irregular bands, which enclose the principal bloodvessels and unite the viscera to each other. Sometimes there are processes filled with oily fat representing the omentum.

In the *Branchiostoma* the œsophagus commences at the bottom of the buccal cavity behind the opening of the branchial sac, between the latter and the spinal axis, and after a short course terminates in a simple dilatation, which forms the stomach. About the middle of the branchial sac the alimentary tube becomes imbedded in the liver, and terminates in a delicate intestine, which extends to the anal opening.

Lymphatic system.—The principal lacteal vessels are situated near the large branches of the cœliac and mesenteric arteries and veins, and the large lymphatic trunks derived from the spleen, liver, and pancreas, accompany the chief bloodvessels of those parts.*

The lacteals and lymphatics of the assistant chylopoietic viscera are much larger in proportion to the bloodvessels than in Quadrupeds, Birds, or even in Reptiles. Their branches communicate with each other freely and repeatedly, and instead of uniting into one or two trunks, they form a right and left plexus, which are continued undiminished in size till they are about to join with the lymphatic system of the rest of the body. Neither the lacteal nor lymphatic vessels are quite cylindrical, but by being contracted a little in many places seem to be jointed, so that the anatomist would expect to find numerous valves in their course, yet these are entirely wanting, except at the termination of the whole system.

The lacteals terminate in a very remarkable structure, which is situated along the great curvature of the stomach. This consists of an elongated viscus, the interior of which is entirely cellular, so that, when prepared by inflation and drying, its internal texture resembles the cancellated structure of bones, being composed of a great many cells of very irregular shapes, and all communicating with each other, so that probably this cellular viscus may perform the office of the absorbent glands of other animals, which in Fishes are totally wanting. Pursuing the right and left plexuses formed by the lacteals and lymphatics of the chylopoietic organs, we are led upwards along the sides and back part of the œsophagus to the sides of the spine and of the inferior venæ cavæ, and

* Monro, Structure and Physiology of Fishes, fol. 1785.

near to large veins covered by strong cartilages, which resemble our clavicles, and which therefore may be called *subclavian veins*. Towards these all the lymphatic vessels of the body are directed, the lymphatics of the kidneys and organs of generation with those of the tail and inferior parts ascending, those of the flesh and side fins of the trunk of the body running inwards, and those of the superior parts and of the brain, organs of the senses, heart, and gills, descending.

The branches of the lymphatic vessels form larger angles where they terminate in their trunks than are found in the veins, and the smaller branches are connected by transverse canals. The large lymphatics of the muscular organs, near their joining with the lacteals, are collected together in the most simple manner, without forming such intricate plexuses as are found in the course and near to the termination of the lacteal vessels: the lymph from the head and thorax in particular is conveyed chiefly by a single trunk, which receives large lateral branches from the adjacent parts. At last a single vessel on each side of the fish, and in which there is no dilatation or large receptacle, receives all the chyle and lymph, and terminates in the subclavian vein of the corresponding side very near its junction with the internal jugular vein, or nearly in the angle which these two vessels form by their joining. The blood is prevented from getting into these two vessels by a pair of valves placed at the termination of each.

In the osseous Fishes the course of the lymphatics has been traced both by Monro and Hewson,* principally in the *Gadidæ* and the Salmon: their general arrangement has been described above.

Four lymphatic vessels which terminate in the subclavian receptacles chiefly merit attention. The first conveys the lymph from the ventral parietes, from the ventral and pectoral fins, and from the heart. The second runs up the side of the fish parallel to the great mucous duct, and brings the lymph from the principal muscles of the tail and body. The third is deep-seated and conveys the lymph from the spine, spinal medulla, and upper part of the head, while the fourth lymphatic vessel, or rather plexus of vessels, brings the lymph from the brain and organs of the senses, and from the mouth, jaws, and gills.

The two receptacles into which all these vessels open communicate freely with each other by wide canals, which pass chiefly behind the heart and œsophagus, and each ultimately empties itself into the upper end of its corresponding vena cava inferior, contiguous to the termination of the internal jugular vein, the communications between the lymphatic and venous systems being guarded by valves.

It will be seen from the above description that the lymphatic system of Fishes offers several remarkable peculiarities when compared with what is met with among the higher Vertebrata, amongst which may be noticed the total want of lymphatic glands, and the absence of valves in the absorbent trunks. Owing to this latter circumstance, nothing is more easy than to inject them from trunk to branch, and thus display their minute ramifications with the greatest ease. In this manner Mr. Hewson detected in the Cod a beautiful net-work of lymphatic vessels situated between the muscular and villous coats of the intestine, something analogous to what exists in the Turtle; but in Fish it is more evident that there can be no deception, seeing that the injection is contained in cylindrical vessels, not diffused in cells, as is the case in the reptile. If mercury be injected into this net-work, it spreads over the intestine; and if the intestine be inverted and slightly pressed, it can readily be seen to pass into the villi of the intestinal mucous membrane. In the stomach, however, the absorbents have a different arrangement. When minutely injected with mercury, they are seen to pass through the external coats, dividing into smaller and smaller branches, without any appearance of a net-work between the muscular and the villous coat, so that the absorbent vessels of the stomach manifestly exhibit a different arrangement from those of the intestine.

By adopting a similar mode of injecting from trunk to branch, Dr. Monro succeeded in demonstrating numberless lymphatics in the brain, eye, ear, and nose, in all of which organs their existence had been previously doubted; and, also, in proving that their ramifications in the rest of the body were far more extensive than had been supposed. He, moreover, points out another circumstance of considerable importance in a physiological point of view, viz., that on examining the minute branches of the lymphatics, they are found to consist of an immense number of anastomosing canals, many of which enter the neighbouring lymphatics at right angles instead of being directed towards the heart, by which means a net-work is produced so very intricate that, when a small portion only is examined, it is difficult or next to impossible to ascertain what has been the natural course of the lymph; it is therefore evident that, from the great number and unfavourable direction of these canals, general pressure cannot in this case be a chief cause of the progressive motion of the lymph, but that each vessel must contribute to its progress by a well-regulated action.

Another remarkable circumstance is stated by Monro in connection with the lymphatic vessels, namely, that in the Skate they open by patulous orifices situated upon the back of the Fish, of sufficient size to allow not only air, but water, milk, quicksilver, and even oil of turpentine coloured with vermilion, to be discharged upon the surface of the skin, even when the force employed in injecting these fluids was very slight, and no extravasation was produced into the cellular tissue either under the skin or in the muscular interstices. The function attributed to these open vessels by Monro is, however, even if they exist, quite hypothetical, namely, that they are for the purpose of absorbing from the ocean the fluid

* Phil. Trans. for 1769.

which is interposed between the skull and the surface of the brain.

Organs of respiration.—The respiration of Fishes is purely aquatic, the oxigenization of the blood being accomplished throughout the entire class by its exposure to the oxygen dissolved in the surrounding medium as it passes through the network of extremely minute vessels that is spread out over the extensive surfaces furnished by the gills or branchiæ.

These organs consist of vascular fringes or laminæ placed on each side of the neck, over which, in the great majority of species, the water taken in at the mouth is made to pass as it issues through the opercular cavities; and in this way the branchial surfaces, being perpetually bathed with aerated water, perform the same office as the lungs of an air-breathing animal.

But while respiration is thus accomplished throughout the whole class by means that are essentially similar, there are several modifications in the mechanical arrangement of the respiratory apparatus, each of which will demand our especial notice.

Throughout all the extensive division of osseous Fishes (with the exception of the *Lophobranchii)* the construction of the breathing organs will be found to accord with the following general description. To the external convex surface of each of the four branchial arches *(fig.* 522) is attached a double series of flat, elongated, cartilaginous laminæ, tapering gradually towards their extremities, the whole forming a crescent-shaped pectiniform framework, over which is spread the highly vascular membrane that constitutes the respiratory surface. On making a transverse section of the gill it is found that towards their base, whereby they become attached to the branchial arch *(fig.* 520, *b*), the two series of branchial laminæ are united to each other, and, moreover, the structure of each leaflet of the branchia becomes apparent. The branchial artery (*c*), whereby the blood is brought to the gills for the purpose of respiration, is seen running along the convexity of the supporting arch in the middle of the base of the branchial laminæ opposite each pair, of which it gives off two branches, which pass outwards to the end of the substance which unites the two layers of gills at their bases, and then severally subdivide, one of the ramuli extending along the internal margin of each branchial lamina to its extremity, the other retrograding to its base. From these two ramuli minute transverse vessels are given off, which distribute the blood over the general surface of the laminæ, and ultimately form the branchial veins, from which the systemic artery is continued. Besides the respiratory laminæ the branchial arches support a series of unvascular processes, which project from their concave margins, and serve to prevent substances taken into the mouth from escaping through the branchial fissures and thus getting among the gills; these processes in the Mullet (Mugil chelo) are extremely beautiful, forming long and delicate fringes along the concavity of each branchial arch, adapted to bar the passage of minute or finely comminuted food through the branchial interspaces. These internal unvascular appendages to the branchial arches act, therefore, the same part as the epiglottis of mammiferous animals. Frequently there are likewise tubercular projections from the contiguous margins of the concave surfaces of the branchial arches, for the purpose of preventing the gills from becoming too closely approximated to each other, and thus interfering with the free circulation of the blood over their surfaces.

Diagram of the circulation of the blood through the branchial leaflets.

b, section of branchial arch; *a*, branchial artery; *c*, branchial vein; *d*, *d*, *e*, *e*, the arterial and venous trunks derived from them.

The mechanism of the respiratory process is, therefore, in these osseous Fishes exceedingly simple. The water which is constantly taken into the mouth passes through the branchial fissures, and is forcibly driven by the simultaneous action of the branchial arches of the os hyoides, of the palato-temporal flaps, and of the opercula, through the interspaces of the gills, and thus passes out through the wide fissure upon the side of the neck beneath the branchiostegous membrane.

In such genera as have this external opening very large and patulous, as it is, for example, in the Herrings and numerous other races, the death of the fish ensues almost immediately on its removal from its native element, not so much on account of a deficiency of oxygen wherewith to aerate the blood in the branchiæ, seeing that that might be derived from the atmosphere, but because the gills, being no longer floated out, collapse, and thus, by preventing the passage of blood through the delicate vessels which ramify over the branchial laminæ, put a stop to the circulation as completely as strangulation could do; but in some genera a provision is made to permit of a more lengthened existence out of the water where the habits of the fish render such an arrangement necessary. In the whole tribe of Eels, for example, the external fissure is removed very far back and reduced to a very small vertical slit, converting the cavity wherein the branchiæ are lodged into an elongated chamber, wherein a considerable quantity of water can be retained: in such Fishes, therefore, the circulation of the blood is by no means put a stop to by taking the fish out of the fluid it usually inhabits, but, on the contrary, many species can exist for a considerable length of time in the air, and even make their way to a distance from their native ponds, the water so retained in contact with the branchiæ continually absorbing from the air a sufficiency of oxygen to carry on the respiratory process.

An important group of Fishes (the "*Pharyngiens labyrinthiformes*" of Cuv.) are characterized by a very peculiar formation of the anterior superior pharyngeal bones, which enables them to live out of the water for a considerable length of time, so that many of them, as we are assured by authors, not unfrequently come on dry land, and even, as in the case of the *Anabas scandens*, or climbing Perch, mount into trees, a faculty for which they are indebted to the following remarkable conformation.

Their inferior pharyngeals and the posterior of their superior pharyngeal bones present the usual arrangement and are studded with teeth, but the two anterior pharyngeals on each side are spread out into thin laminæ folded upon themselves in divers ways, so as to form a light complicated mass, (which Cuvier* compares to a curly cabbage, or to certain forms of laminated eschars and millepores,) over which numerous vessels are distributed, but whether derived from the branchial artery or the aorta remains uncertain. In order to lodge these singular cellular organs the head is considerably dilated in breadth, and with the same intention the cranium is produced upwards by a vertical crest so as to increase the height of the lateral chambers in which the foliaceous masses are lodged. Externally, each of these chambers is partially covered by the bones of the cranium and by the opercular pieces; and when the operculum is raised, a membrane is seen to be tightly expanded between it and the opercular bone so as to enclose the cavity, leaving only a small aperture of communication with the exterior, which leads equally to the labyrinthiform apparatus and the branchial chamber. This bony labyrinth, therefore, so carefully enclosed on all sides, and which receives water equally with the branchiæ whenever the fish opens its mouth, will retain the water so taken in between its lamellæ wherewith to moisten the branchiæ for a considerable length of time, so that the fish may live for hours or perhaps even for days out of the water.

The *Lophobranchii* form a remarkable group, distinguished from all other races of osseous Fishes by the peculiar structure of their branchial organs. In these, called from their peculiar shapes and external armour "pipe-fishes," (*Syngnathus*, *Hippocampus*, *&c.*) the vascular fringes appended to the branchial arches, instead of consisting of lamellæ arranged in a pectinated form, are collected into tufts arranged in a double series along the convexity of each branchial arch. The essential character of these tufts varies, however, in no respect from that of gills of the ordinary construction, and in like manner the water passes from the mouth through five apertures leading from the pharynx into the branchial chamber, whence, after bathing the tufted gills, it escapes through a single small opercular fissure.

The Sturgeons (*Sturionidæ*), which in many points of their economy seem intermediate between the osseous and cartilaginous Fishes, resemble the former in the disposition of their organs of respiration. The gills of the Sturgeon are constructed precisely in the same manner as in ordinary osseous Fishes, only differing in some respects as to form, the branchial arches being more bent and the vascular laminæ united for a greater extent; the respired water, moreover, escapes in like manner through a single opercular slit.

In the Plagiostome cartilaginous Fishes ("Chondropterygii à branchies fixés," Cuv.) the mechanical arrangement of the branchial organs presents very important modifications, the water which passes from the mouth over the gills no longer escaping through an opercular opening, but being expelled through five distinct orifices situated on each side of the body. In the *Sharks* and *Rays* the condition of the breathing organs is essentially similar, so that the same description will apply to both. The four branchial arches in these Fishes are of a soft cartilaginous consistence, and instead of hanging free in the branchial chamber as they do in the osseous genera, stretch quite across that cavity to have their external margins fixed to its outer walls, thus dividing it like so many bulk-heads into five distinct compartments, which have no communication with each other. A wide branchial fissure admits water from the pharynx into each of these compartments, which after passing over the gills is expelled by as many orifices situated upon the exterior of the body, the external openings being situated upon the sides of the throat in the Squalidæ (*fig.* 506, *q*, *q*, *q*), but in the Skates, in consequence of the lateral extension of the body, they are placed upon the ventral surface. The gills themselves are broad vascular membranes spread out over the opposite faces of each cartilaginous septum, so that every compartment of the branchial chamber has its walls tapestried with a respiratory surface, and forms a kind of bag lined with innumerable blood-vessels, through which the water must pass in its course from the mouth to the external openings upon the sides of the neck.

The branchial membrane which thus covers the opposed walls that bound the respective cavities into which the gill-chamber is divided, is entirely made up of numerous plicated, vascular lamellæ, each of which is gathered into close-set transverse folds sustaining the minute ramifications of the branchial vessels; and these again may be observed with a lens to be in like manner transversely plicated, thus presenting in the aggregate a surface of vast extent to the influence of the respiratory currents. In the anterior branchia the vascular layer is of course affixed only to the posterior surface of the supporting membrane, the opposite side being supported by cartilaginous rays.*

* Hist. des Poissons, tom. 8.

* Monro makes the following calculation rela-

In the Sharks the orifices of the pharynx leading into the branchial chambers are guarded by cartilaginous pyramidal processes; but in the Skates, which have the cartilaginous arches much less perfectly formed, no such defences are visible.

The Cyclostomatous cartilaginous Fishes, from the peculiarities of their habits, require another modification in the construction of the organs of respiration, seeing that, whilst they rest fixed by their suctorial mouths to the surfaces of stones or other foreign bodies, or while they are compelled to remain with their heads deeply plunged into the flesh of the prey upon which they live, the admission of water into the mouth and its subsequent expulsion through pharyngeal fissures would, in their case, be impracticable.

In the Myxine or Hag-fish the branchial apparatus presents externally seven round holes placed in a line along each side of the neck, and situated very far back in comparison with the usual situation of the gill-openings. Each of the seven lateral openings leads internally into a flattened circular cavity, which likewise communicates by a special canal with the interior of the pharynx. When opened, each gill-sac is found to have its lining vascular membrane gathered into closely set folds, which in turn exhibit, when accurately examined, smaller plicæ, and thus a great superficial extent of respiratory membrane is secured, much in the same manner as in the case of the *Raidæ;* indeed, the general disposition of the whole apparatus is essentially similar in the two groups, the great difference being that whereas in the plagiostome genera the water passes in at the mouth and out at the gills, in the Cyclostomata it alternately passes in and out through the same orifices by a mechanism which is best exhibited in the Lampreys (*Petromyzon*).

In the last mentioned genus of Cyclostomatous Fishes, the seven holes which lead to the breathing organs are seen, on removing the skin, to be supported by a curiously contorted framework of cartilaginous pieces, which we have already noticed as being the exaggerated representatives of the sternal ribs met with in the Sharks, and which we shall subsequently see in a much more highly developed condition in Branchiostoma. These form a kind of elastic thorax around the region of the body where the branchiæ are situated, which is made to perform alternate movements of contraction and dilatation, whereby the water is perpetually sucked in and again expelled through the external openings (*fig.*521, *i*, *i*). The branchiæ themselves (*h*, *h*) present nearly the same structure as in the Myxine, consisting of as many distinct

Fig. 521.

a, mouth with its teeth; *b*, pharynx; *c*, opening of tube from the back of the head; *d*, cavity communicating with the respiratory sacculi of both sides; *e*, commencement of œsophagus; *f*, cartilaginous process connected with hyoid tooth, likewise marked *d*; *g*, muscles of sucking disc; *h*, *h*, respiratory cavities and branchiæ contained therein; *i*, *i*, external openings of do.; *m*, cartilaginous sac investing the pericardium.

sacculi as there are external openings, ranged along the sides of the neck, each sacculus having its vascular lining membrane finely plicated in order to increase the extent of surface to be exposed to the respired element. Every branchial sacculus, in addition to its communication with the exterior through the lateral openings of the neck, has a passage that leads into the pharynx (*d*), so that by the intervention of the pharyngeal cavity the respiratory sacculi of the opposite sides of the body are made to communicate with each other, an arrangement which explains the circumstance, that when the breathing holes of one side of the Lamprey are kept above water, the respired fluid which enters the submerged orifices, after traversing the pharynx, fills the branchial chambers of the opposite side, and is forcibly ejected therefrom

tive to the extent of the respiratory surface presented by the gills of Fishes to the action of the surrounding medium. On each side of the body of a *Skate*, says he, there are four double gills, or gills with two sides each, and one single gill; or there are in all eighteen sides or surfaces on which the branchial artery is spread out. On each of these sides there are about fifty divisions or doublings of the membrane of the gills. Each division has on each side of it 160 subdivisions, doublings, or folds of its membrane, the length of each of which in a very large skate is about one-eighth of an inch, and its breadth about one-sixteenth of an inch, so that in the whole gills there are 144,000 subdivisions or folds, the two sides of each of which are equal to the 64th part of a square inch, or the surface of the whole gills in a large skate is equal to 2.250 square inches, that is, to 15 square feet, an expanse equal to the whole external surface of the human body.—Structure and Physiology of Fishes, p. 15.

through the exposed apertures. There is, moreover, another remarkable arrangement in the Lampreys, whereby, notwithstanding the suctorial character of their mouths, the members of this genus have the character of their respiratory apparatus approximated to that of other races of Fishes. This consists in the presence of a small tubular orifice situated in the middle of the back of the head, just in front of the eyes, which leads downwards into the pharynx (*b*,) into which it opens by the orifice *c*, so that water can enter by this passage while the mouth is kept immoveably fixed to the surface whereunto the Lamprey has attached itself.

The respiratory system of *Branchiostoma* is highly curious in its arrangement. It may be said to consist of two portions, a hyoid apparatus of a very remarkable kind, and a respiratory or branchial sac enclosed by a series of thoracic ribs, both of which will require a particular description before we proceed further with this part of our subject.

Hyoid apparatus. — The hyoid apparatus supports the mouth and guards its entrance, the oral aperture, which is in the form of a longitudinal slit, being bounded on each side by a series of hyoid cartilages, each of which consists of several pieces articulated together so as to form a continuous chain, which gradually diminishes in thickness towards its anterior extremity. To every one of these pieces is attached a cartilaginous arch composed of two cartilaginous stems, which are armed with delicate denticulations, and covered with a fine membrane, which is extended along the base of the posterior ones like a thin interdigital web, which forms the margin of the mouth.

Branchial cavity.—This is situated behind the hyoid apparatus, and consists of a kind of thorax composed of upwards of a hundred transparent, cartilaginous, and hair-like arches, the upper extremities of which are fixed in two streaks of a soft white substance, which runs along on each side of the inferior surface of the chorda dorsalis on the sides of the inferior longitudinal ligament. The inferior extremities of the ribs terminate in a more complicated manner. Each alternate rib bifurcates. The inferior branch on each side meets its fellow of the opposite side at an angle in the median line, while the superior branch likewise curves up and meets the corresponding division of its opposite, while the non-bifurcated ribs, which are shorter, terminate in a line with the bifurcation of the neighbouring pairs. There are, moreover, slender cross pieces joining the neighbouring ribs together, disposed in an alternating series like the joinings of stones in masonry. The heart is situated at the posterior extremity of the branchial sac between its posterior extremity and the commencement of the liver; it consists, according to Costa, of two delicate cavities situated transversely above and a little to the right of the intestine. These cavities ("orecchiette") communicate, and the blood passes from one to the other, being driven forward by rapid pulsations. From the second cavity of the heart the blood is driven into the trunk of the branchial artery, which is situated between the intestine and the point of attachment between the branchial ribs and the spinal column. The course of the blood is at first rapid and very distinct, owing to the size of the branchial artery being considerable; but as it runs forwards, it expends itself in numerous spiral vessels, which, accompanying all the thoracic arches and their transverse attachments, thus present a considerable surface and constitute the branchiæ of the fish. Finally, towards the anterior extremity of the respiratory cavity the branchial artery has become so much reduced in size as to be no longer distinguishable.

In addition to the extensive surface furnished by the respiratory sac there are three vascular lamellæ situated on each side of the fauces, to which Costa applies the name of opercular branchiæ, believing them to be analogous to the branchiæ attached to the opercula of the Sturgeon and other Fishes; these receive their supply of blood from an arterial trunk that surrounds the back part of the roof of the mouth.

Heart.—The heart of Fishes (*fig.* 522, C, A) is situated beneath the throat immediately behind the inferior terminations of the branchial arches, where it is lodged in a compartment partitioned off from the cavity of the abdomen by a strong tendinous septum, which forms a sort of immoveable diaphragm. In the Lampreys the heart is moreover encased in a cartilaginous capsule (*fig.* 521, *m*) formed by the posterior portion of the cartilaginous frame-work that surrounds the branchial apparatus.

In the course of the circulation the heart of Fishes is interposed between the systemic veins and the organs of respiration, its office being to propel the venous blood received through the venæ cavæ into the gills, whence it is conveyed by the arterial system to be distributed to the body without the intervention of any contractile cavity devoted to its propulsion through the arterial trunks. For a diagram of the course of the circulation in Fishes the reader is referred to *fig.* 319, vol. i.

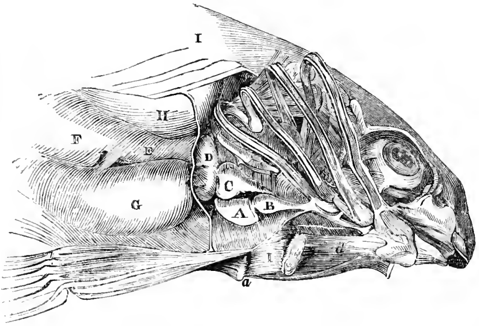
The heart of a fish is therefore at once distinguishable from that of any other vertebrate animal by the circumstance of its consisting of only two cavities, an auricle and a ventricle, the former of which receives the blood from the body, while the latter diffuses it over the branchial surfaces. The auricle (*fig.* 522, C) is very capacious, having its walls made up of intercrossing muscular fibres, which from their frequent decussations present internally a reticulate appearance. It receives the venous blood from a sinus (D), formed by the conjoined cavæ through a single orifice, which is guarded by two large semilunar valves, arranged so as to prevent the reflux of blood into the veins.

The ventricle is considerably smaller than the auricular cavity, with which it communicates by a wide lateral orifice. Its shape in the osseous Fishes is most usually somewhat four-sided, and its muscular walls, considerably thicker than those of the auricle, present internally a strong fasciculated appearance. The auriculo-ventricular opening is generally guarded by two strong valves ordinarily of a semilunar shape, but sometimes, as for example in the Sturgeon, resembling the tricuspid valve of the heart in Mammalia, having chordæ tendineæ passing from its margin to the muscular walls of the ventricle.

In other cases again, as in the *Sun-fish* (*Orthagoriscus Mola*), the auricular aperture is guarded by four valves, two small semilunar valves being placed at right angles with and on the auricular side of the two large semilunar valves that usually exist in this situation.

The branchial artery (*fig.* 522, B) which arises from the ventricle is very different in character from an artery of ordinary appearance, its walls being exceedingly thick and muscular, and frequently fasciculated internally; its cavity is moreover dilated so as sometimes to equal in capacity that of the ventricle itself. This dilated portion of the branchial artery, to which the name of

Fig. 522.



Heart and principal vessels of Perch.

bulbus arteriosus has been given, is in fact almost equivalent to a second ventricular chamber, and doubtless by its contractile power forcibly assists in propelling the blood through the gills.

The origin of the *bulbus arteriosus* is always guarded by strong valves, of which there are frequently only two of a semilunar form, but occasionally the valve is made up of four semilunar membranous folds.

But it is not only at the commencement of the bulbus arteriosus that valves exist, these defences being frequently multiplied in this portion of the circulating system of Fishes in a very extraordinary manner. Thus, in the Sturgeon there are three series of semilunar valves, two at the commencement and one at the termination of the bulb, the last being the strongest and most perfectly formed. Those at the base are much thickened at their margins, which are attached to the parietes of the bulb by small chordæ tendineæ. The two lower valves are each made up of four semilunar folds, whilst in the upper one there are five. In the Skate (*Raia Batis*) there are five distinct sets of valves, increasing in size to the last row, which is at the termination of the bulb.

The most probable reason of this unusual fortification of the valvular apparatus of the branchial artery in Fishes is that, owing to the depth to which some of them descend or at which many races dwell habitually, as for example, the ground-frequenting Skates, the pressure upon the surface of the gills must render the passage of the blood over the branchiæ very difficult, so that unusual care has been taken in strengthening the bulbus arteriosus itself, and likewise the valvular structures in its interior.

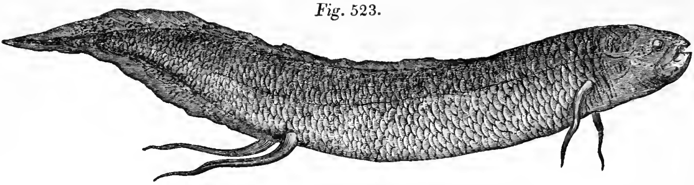
The *bulbus arteriosus* ultimately resolves itself into the branchial artery, which gives off the trunks that supply the venous blood to the gills.

Vascular system.—The general course of the blood during its circuit through the body of a fish has been already described in a preceding article (see CIRCULATION); we shall therefore limit ourselves in this place to describe the disposition of the principal vascular trunks, and the manner in which the circulating fluid is distributed to different parts of the system. The vessels formed by the division of the branchial artery run in a deep groove along the convexity of each branchial arch external to the branchial vein, which runs in the same groove, taking an opposite course. The branchial vein, as we have already seen, is formed by collecting all the venules from the branchial laminæ of the corresponding gill, and thus carries only the blood which has undergone the process of respiration. The branchial artery and the branchial vein are therefore placed under precisely inverse circumstances with respect to each other; the former diminishing continually in size as it mounts upwards towards the dorsal aspect of the gills by giving off arterioles to the branchial laminæ; the latter increasing in bulk as it proceeds in the same direction, owing to the constant accession of little veins derived from the fringes of the gills. In the Skates there are two branchial veins to each gill, which, however, ultimately become united into one trunk.

No sooner do the branchial veins issue from the dorsal extremities of the branchial arches than they assume the texture and the function of arteries, and ultimately all joining with each other and with those of the opposite side, they constitute by their union the aorta, by which the blood is distributed to the general system. Before their union into a single aortic trunk there are arterial vessels given off from the branchial veins themselves; thus the anterior give off, even before they leave the branchial arch, several vessels to supply the head and adjacent parts, while the heart itself and the neighbouring region beneath the throat likewise receive their supply of arterial blood through a twig derived immediately from a branchial vein.

The aorta, formed, as has been stated, by the union of all the branchial veins without the inter-

Fig. 523.



Lepidosiren.

position of any contractile organs corresponding with the left side of the heart of Mammalia, immediately proceeds to give off branches to the trunk and abdominal viscera. Almost close to its commencement it sends into the abdomen the large visceral trunk, which supplies all the abdominal viscera with blood, being distributed to the liver, to the stomach, to the intestines, to the spleen, to the generative organs, and to the swimming bladder.

After giving off the above large visceral artery, the aorta continues its course backwards beneath the bodies of the supra-abdominal vertebræ; but as soon as it reaches the post-abdominal vertebræ, it enters the canal formed by their inferior arches (*hæmapophyses*), through which it passes backwards to the tail. During its passage through the abdomen the aorta furnishes arteries right and left to the kidneys, between which it lies; but with this exception all its branches, which are given off opposite each vertebra like the intercostal arteries of the human subject, are distributed to the muscles of the trunk.

Venous system.—All the arteries given off from the aorta are accompanied by corresponding venous branches, through which the blood is returned into two large veins, one above and the other beneath the vertebral column. The former running with the spinal cord in the superior vertebral canal, the other being in contact with the aorta through its whole length, these great veins frequently intercommunicate by means of inosculating branches, and the inferior one ultimately terminates in the great venous sinus that opens into the auricle of the heart. This sinus likewise receives through several different trunks the veins from the liver, from the generative organs, from the kidneys, from the pectoral and ventral fins, from the branchial organs and other parts of the throat, and likewise from the head, the blood derived from the head having been previously collected in a large sinus.

The highest form of the respiratory and circulatory apparatus met with in Fishes is found in the Lepidosiren, a remarkable genus found in the river Amazon and in the Gambia.* In this interesting creature the gills of the fish are combined with rudimentary air-sacs which perform the office of lungs, and, in fact, the whole arrangement of its circulatory system approximates so nearly that of the amphibious reptiles that, were it not for its otherwise completely icthyic characters, it might almost be regarded as belonging to that order of Reptilia with which it forms an interesting link of connection. The branchiæ of the Lepidosiren consist of separate elongated filaments attached by one extremity to the branchial arches, which are four in number. These cartilaginous branchial arches are developed on each side in the submucous tissue, and are not attached either to the os hyoides below or to the cranium above. The membrane covering the third, fourth, and fifth arches is minutely papillose, while the margins of the first and second are finely denticulated, and between these are five branchial apertures, or interspaces, through which bristles are represented as passing in the accompanying figure, (*fig.* 524, 1, 2, 3, 4, 5.)

The gills do not form any external projection as in the gill-bearing Perennibranchian Amphibia, but are contained in a moderately capacious branchial chamber, the parietes of which are formed by a mucous and muscular stratum, the external outlet being a vertical slit situated immediately anterior to the filamentary pectoral limb.

"Thus," observes Professor Owen, "although the organs of respiration through the medium of water correspond in all essential points with those of the true fishes, yet the gills approximate in their filamentary form to those of the Perennibranchiate Reptiles. And again, although the gills are four in number on each side, as in the osseous fishes, yet the number of branchial apertures and arches corresponds with that which characterizes the higher cartilaginous fishes. So that, while we perceive, even in the organs for breathing water, a ten-

Fig. 524.

a, first lobe of the tongue; *b*, second lobe of the tongue; *c*, pharynx; *d*, pharyngeal valve; *e*, opening of larynx; *f*, laryngeal or thyroid cartilage; 1, 2, 3, 4, 5, interspaces between branchial arches.

* Professor Owen, Description of Lepidosiren annectens. Trans. of Linnæan Society, vol. xviii.

dency towards the amphibious type, we find at the same time that the branchial as well as the osseous system manifests a most interesting transitional structure between the plagiostomous and osseous fishes. We have next to consider that part of the respiratory system which is organized for breathing immediately the atmospheric air, or the lungs; for I do not know how otherwise to designate, according either to their physiological or morphological relations, those organs which in the technical language of the ichthyologist would be termed the swimming or air-bladder. The trachea, or to use the same technical and partial nomenclature, the "ductus pneumaticus," is a wide short membranous tube, as in the Perennibranchiate Reptiles. The glottis (*fig.* 524, *c*,) opens near the posterior part of a long rudimental thyroid cartilage (*f*): a few lines posterior to the *isthmus faucium* the opposite end of the trachea dilates into a membranous sac, which communicates by two large lateral apertures with the lungs. These are widest at their anterior extremities, and gradually decrease in diameter to the cloaca, behind which they terminate each

Fig. 525.

Respiratory and circulatory apparatus of Lepidosiren annectens, after Owen.

a, auricle; *b*. ventricle laid open to show the termination of the vena pulmonalis, in which a black bristle is placed; *c*, bulbus arteriosus laid open; *d*, pericardium; *e*, vena cava abdominalis; *f*, vena pulmonalis; 1, 2, 3, 4, 5, 6, branchial arteries of left side; *m*, pulmonary artery; *n*, pulmonary vein.

in an obtuse point (*fig.* 525). They are lodged in the dorsal angle of the abdominal cavity behind the kidneys, and are attached by cellular tissue to all the surrounding parts, and especially to the ribs, of which they bear the impressions on their posterior surface. The anterior part of each lung is divided into four or five small lobes, behind which it takes on the form of a simple compressed bag, and so continues to its posterior extremity. The parietes of the lung present a moderate thickness throughout, and the whole of the internal surface is cellular, the cells having the same proportional size and form as in the respiratory portion of the lung of a serpent. The cells are largest and most subdivided at the anterior part of the lung, the livid colour of which, in the specimen dissected" by Professor Owen, "attested the great vascularity of the part."

In tracing the arrangement of the circulatory system of the Lepidosiren the same intermediate type of structure is most interestingly conspicuous. The heart consists of an auricle, (*fig.* 525, *a*,) ventricle, (*b*,) and a bulbus arteriosus. The vena cava (*e*) terminates in the right side of the auricle; it is joined by the two superior cavæ and by the single large pulmonary vein; this vein (*f*) does not, however, communicate with the sinus, but passes along entire and adherent to the inner surface of the vena cava as far as the auriculo-ventricular aperture, where it empties its contents into the ventricle by a distinct orifice protected by a cartilaginous valvular tubercle. It needed only that the pulmonary vein should have been dilated before its termination, in order to have established a bi-auricular structure of the heart, as in the Amphibious Siren. The same functional advantage is, however, thus secured to the Lepidosiren with a maintenance of the simple dicælous type of the heart of the fish; this continuation of the pulmonary vein preventing the admixture of the respired with the venous blood, until both have arrived in the ventricle.

The ventricle (*fig.* 525, *b*) is extremely small; its parietes are thick and reticularly muscular; a small round orifice leads to the bulbus arteriosus (*c*). This is formed by a short spiral turn of the dilated aorta, which is concealed under a simple continuous fibrous coat. The area of this part of the vessel is almost entirely occupied by two continuous valvular projections or their processes, which are attached by one edge to the internal surface of the aorta, and have the opposite margin projecting freely into the arterial cavity.

The aorta in this remarkable species fulfils at once the office of a systemic, a branchial, and a pulmonary artery; it distributes on each side six vessels, (*fig.* 525, 1, 2, 3, 4, 5, 6,) corresponding to the six branchial cartilaginous arches. The mucous membrane is produced into a branchial fringe on the convex side of the first, fourth, fifth, and sixth branchial arches, and the corresponding arteries are minutely subdivided before they are continued to the dorsal side of the pharynx; these four pairs of vessels are therefore true or functional branchial arteries. The mucous membrane merely invests with a simple fold the second and third branchial arches; and the corresponding arterial trunks undergo no subdivision as they wind round them, but are continued entire (as in the Amphiuma and Menopoma) to their termination at the opposite side of the vascular circle. The branches which afterwards unite to form the single pulmonary artery on each side are given off from near the termination of the second and third pairs of the primitive aortic trunk, which thus combine the functions of both systemic and pulmonary arteries. The pulmonary artery, formed by the union of the branches from the second and third branchial arteries, descends between the vena cava (*fig.* 525, *e*) in front, and the left branch of the vena pulmonalis (*f*) behind to the interspace to the lungs; here it distributes branches to the anterior lobes, and then divides; each division extends along the mesial side of its corresponding lung to the extremity. The blood distributed by the capillaries of this artery over the cells of the lung is collected into a vein (*n*) which returns along the lateral or outer margin of the lung as far as the commencement of the lobulated part; here it crosses obliquely the anterior surface of the lung and unites with its fellow. The common pulmonary vein runs parallel with and behind the vena cava for a few lines, then obliquely pierces the pericardium, and enters the sinus formed by the expansion of the vena cava, and continues attached to the parietes of that sinus till it reaches the auriculo-ventricular aperture, where it terminates close behind the cartilaginous knob before mentioned.*

Portal system of veins.—All the blood derived from the stomach, from the intestines, and from the spleen, is collected into one or sometimes into several trunks, which convey it into the liver for the elaboration of bile precisely as in other races of Vertebrata. In some genera, however, more especially the *Cyprinidæ*, the lobes of the liver are so intervolved with the intestinal folds, that the venous blood from the intestines enters the liver through innumerable small branches, none of which are of sufficient size to be regarded as a main trunk of the portal vein. Rathke,† indeed, observes, in relation to this subject, that the vena portæ of Fishes exhibits a kind of transition in its arrangement, a sort of tendency to perfection indicated by progressive concentration of the venous trunks according to the following scale:—As an improvement upon the portal system of the Ciprinidæ, in *Cottus scorpio* all the veins bringing the blood from the abdominal viscera form three principal trunks, which enter the liver separately. In *Cobitis fossilis* most of these veins are found united into two trunks, which penetrate the liver separately; but besides these there are some straggling branches which keep themselves independent of the two great veins. In the *Blenny* and the *Pike* there are only two portal trunks. In the *Lump-fish*, the *Shad*, &c., the two trunks are united into one; but there are still small veins which run isolatedly into the substance of the liver; and lastly, in the Eel, the Perch, &c., there is only one vena portæ, as in the most highly organized vertebrate animals.

* See Professor Owen's paper, ubi supra.

† Annales des Sciences Nat. tom. ix. p. 170.

There is a remarkable circumstance connected with the great venous trunk above alluded to which accompanies the spinal cord lodged in the superior vertebral canal, for this vein, although it receives a good proportion of the blood derived from the muscles of the upper part of the trunk, does not empty itself into the venous sinus of the heart, and, from the circumstance of its giving off numerous large branches to the substance of the kidney, has been regarded as forming a renal portal system, similar to that described by Jacobson as existing in Birds. It must, however, be observed that this superior vein communicates very freely with the inferior vein, which indubitably represents the vena cava inferior, and consequently the renal branches may be derived from, and not distributed to, the kidney.

Lateral system of vessels.—Dr. Marshall Hall discovered some years ago a pulsating cavity or heart situated near the caudal extremity of the vertebral column of the Eel, the contractions of which were found to be quite independent of the pulsations of the branchial heart, this organ beating 160 times in a minute, while the pulses of the branchial heart were only 60. This structure, the existence of which only was pointed out by Dr. Marshall Hall, has since been carefully investigated by M. Hyrtl,* and the following is the result of that gentleman's explorations. The organ in question is easily seen by stretching out the tail of an Eel upon a piece of glass, to which it readily adheres owing to the viscid secretion furnished by the skin. Its pulsations are very lively, and it seems surrounded by a transparent areola, which appeared to M. Hyrtl to consist of two sacs. The disorganization of the spinal marrow by means of a wire had no effect upon the number of its pulsations, and even when the branchial heart was tied or the animal cut in two, the caudal heart continued to beat for five or six minutes. The genera in which the caudal heart and the apparatus connected with it were examined, were *Accipenser*, *Salmo*, *Perca*, *Abramis Leuciscus*, *Gadus*, *Gobio*, *Silurus*, *Esox*, *Cyprinus*, *Zeus*, *Lophius*, and several others, so that doubtless the system under consideration is common to the whole class of Fishes.

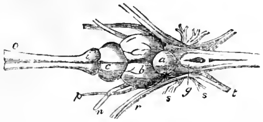
Brain.—The encephalon of Fishes is remarkable for its diminutive size in proportion to the dimensions of the animal, and also with relation to the nerves which are derived from it; in fact it occupies but a very small portion of the cavity of the cranium, the wide interval existing between its surface and the dura mater that lines the cranial parietes being filled up with loose cellulosity filled with fluid, and sometimes containing abundance of oil, or in certain instances, as for example in the Sturgeon and Tunny, of a compact and fatty substance.

It has been remarked that this interval between the cranium and the surface of the brain is much less in young subjects than in adults—a

* Archiv. für Anat. Phys. und Wissenschaftliche Medecin herausgegeben von J. Muller. 1843. p. 124.

circumstance which proves that their brain does not grow in the same proportion as the rest of the body; indeed Cuvier found the dimensions of the brain nearly similar in individuals of the same species, though one might be double the size of the other.

Fig. 526.



Brain of Perch, upper surface. (After Cuvier.)

a, cerebellum; *b*, hollow (cerebral) lobes; *c*, olfactory lobes; other letters as in the two following figures.

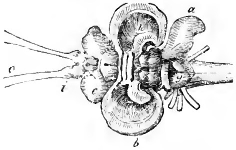
The encephalon consists of a series of lobes situated one behind the other (*fig.* 526), concerning the precise analogies of which no two authors seem to be agreed. In the following account of its general structure we shall therefore closely adhere to Cuvier's masterly analysis of the organization of the brain of the *Perch*, at the same time, however, noticing the opinions of anatomists, and the principal variations, observable in other Fishes, from the form of brain selected for special description.

The anterior pair of lobes (*figs.* 526, 527, *c, c*) invariably give origin to the olfactory nerves, and consequently are very generally called the olfactory lobes of the brain. Their surface is most frequently smooth, but occasionally marked, as for example in the Cod, with slight sulci. Their relative size varies very much, but they are generally, but not always, smaller than the succeeding pair of lobes (*b, b*). They are connected with each other inferiorly by a commissure, which is sometimes double, and the internal fibres of the medulla oblongata may be distinctly traced into their substance.

In front of these olfactory lobes there are generally one and sometimes two pairs of ganglia (*figs.* 526, 527, 528, *i, i*) connected with the origins of the olfactory nerves, which, when very large, might be mistaken for additional lobes of the brain. They are, however, never connected by commissural fibres to their fellows of the opposite side, and the olfactory nerve can be traced along their under surface as far as the proper anterior lobes of the encephalon (*c, c*). Internally they frequently present a ventricular cavity, which communicates beneath the anterior commissure with that of the cerebral masses next to be described.

The second pair of cerebral lobes (*figs.* 526, 527, 528, *b, b*) are of an oval form, and are remarkable from the circumstance that they enclose a wide cavity or ventricle, whence they have been designated by some anatomists the *hollow lobes* (*fig.* 527, *b*). They consist, like the cerebral lobes of the higher Vertebrata, of two layers, which are generally easily separable; the outer layer consisting of grey or cineritious matter, the inner layer of the white or fibrous substance of the brain, the fibres of the latter running transversely so as to line the roof of the ventricular cavity, which is common to both sides of the brain; for although the hollow lobes are united to each other superiorly along the median line so as to form a kind of corpus collosum with a median raphé, there is no septum between the two sides. The fibres lining the ventricular cavity seem to emerge from two semicircular bands of grey matter (*fig.* 527, *h, h*) situated upon the floor of the ventricle.

Fig. 527.



Brain of Perch, with the "hollow lobes" laid open, and the cerebellum turned to the right side. (After Cuvier.)

Letters *a, b, c*, as in last figure; *g*, supplementary cerebellic lobes; *h*, fibres lining the ventricular cavity.

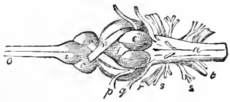
At the bottom of the ventricular cavity there are likewise, in osseous Fishes, two or four tubercles of grey substance placed in front of the base of the cerebellum, and arching over the canal which leads from the large cavity contained in the hollow lobes into the ventricle behind the cerebellum, which it is impossible to consider as anything else but the representative of the fourth ventricle of the superior classes of animals, and the canal of communication as the "*iter a tertio ad quartum ventriculum*" of the human anatomist, the tubercles themselves being evidently the homologues of the *tubercula* quadrigemina.

The external fibres of the medulla oblongata are easily traceable into the lobes we are now considering, which, moreover, are connected with each other by a broad commissure exactly corresponding in situation with the anterior commissure of the human brain. There can, therefore, be no reasonable doubt that the "hollow lobes" of the Fish's brain represent the cerebral hemispheres of the encephalon of Reptiles, Birds, and Quadrupeds, and, with the data above given before us, it is not difficult to point out the analogies of the remaining parts not displayed in the figure. Thus, immediately behind the commissure is a passage leading into the cavity, which corresponds to the third ventricle, and which leads as usual to the infundibulum and towards the pituitary body that occupies its usual situation at the base of the brain.

The internal fibres of the medulla oblongata may be traced forwards into these hollow cerebral lobes, in which they spread out as in the higher animals.

At the inferior surface of the brain, beneath the "hollow lobes" just described, are two oval protuberances (*fig.* 528, *e, e*), which are designated by Cuvier the *inferior lobes*, between the anterior extremities of which is situated the pituitary body *(f)*. These inferior lobes are generally of considerable size, of an oval or kidney shape, and sometimes, but rarely, contain ventricular cavities, which communicate with the third ventricle, and through it with the great ventricles contained in the " hollow lobes;" they furnish fibres of origin to the optic nerves, and it is from the fissure between them and the medulla oblongata that the nerves of the third pair take their origin.

Fig. 528.



Brain of Perch, lower surface. ***(After Cuvier.)***

Letters *a, b, c, g, h*, as in preceding figures; *e*, inferior lobes; *f*, pituitary body; *i*, swelling at commencement of olfactory nerve; *n*, optic nerves; *o*, olfactory; *p, q, r, s, t*, encephalic nerves.

The *pituitary body (fig.* 528, *f)* occupies its usual position on the base of the brain at the extremity of the infundibulum; it is generally of large size in Fishes, and is often connected with membranous and vascular appendages of various forms,—a circumstance which is, however, most remarkable in the cartilaginous Fishes. Occasionally, as for example in the Lophius and the Haddock, the infundibulum is prolonged into a slender filament, and the pituitary body is removed very far forward; but the uses of these parts are as problematical in Fishes as in the other classes of Vertebrata.

The cerebellum *(figs.* 526, 527, *a)* in osseous Fishes is of considerable size, but consists of the median portion only, no lateral lobes being as yet developed, or at least they are only indicated by slight eminences. Its shape is generally that of a blunted cone, the apex of which is bent backwards; but there are instances, as for example the *Mackarel*, in which it is directed forwards, and sometimes it extends so far forwards as to overlap all the rest of the encephalon. Owing to the deficiency of the lateral lobes of the cerebellum there are of course no traces of a *pons Varolii.*

Behind the cerebellum, on each side of the fourth ventricle, and sometimes even covering that cavity, are certain supplementary lobes *(fig.* 527, *g)* which would seem to be peculiar to Fishes, and which are very variable in their proportions, forms, and connections. In most osseous Fishes they consist of two protuberances or swellings of the sides of the medulla behind the cerebellum, which touch each other along the mesial line or are united by a commissure.

In the Cyprinidæ their volume is so considerable that they cover the greater part of the medulla oblongata, and their sides are furrowed with transverse striæ. In the Grey Mullet they are also very large, and their surface is marked with tortuous sulci, giving the appearance of cerebral convolutions. It is, however, in the Triglæ or Gurnards that these lobes are most largely developed, amounting in number to as many as five on each side, and occupying a space equal in length to all the rest of the encephalon, and extending backwards as far as the second vertebra. It is from the last of these lobes that the second pair of spinal nerves is given off, which in this genus supplies the free rays situated in front of the pectoral fins.*

In the chondropteryginous Fishes the structure of the encephalon offers many remarkable peculiarities. Thus, in the Rays and Sharks the proportionate size of the olfactory lobes is enormous, and instead of simply having a commissural communication with each other, they are consolidated into one mass. The hemispheres enclose a capacious ventricle, but there are no distinct fibres visible upon its inner surface, neither are the representatives of the tubercula quadrigemina of osseous Fishes apparent. The cerebellum is of great relative size, but of very variable form in different species; and not unfrequently it is divided into laminæ by deep transverse sulci. The supplementary lobes behind the cerebellum are represented by folds or cords of nervous matter, which are prolonged from each side of the posterior edge of the base of the cerebellum and run backwards along the margin of the fourth ventricle.

The brain of the Tunny *(Thynnus vulg.* Cuv). is remarkable for the extent of the cerebellum, and the complication of the internal tubercles. The olfactory nerves are small and oval. The hollow or cerebral lobes are of very great size, and nearly spherical, with a lateral fissure inferiorly. On opening them, instead of the tubercles generally met with in Fishes, there is found on each side a mass divided into three lobes, which are themselves grooved with a fissure, so that the whole resembles a cylinder or cord having six folds, twelve in all. The cerebellum is larger than the rest of the encephalon, and, arising from the medulla oblongata, curves forwards, overlaying both the hollow lobes and the olfactory lobes even as far as the anterior extremity of the latter, its breadth being little less than half its length. At the posterior part of its base there is on each side a rounded protuberance, different in character from those enlargements which are frequently met with in other Fishes at the commencement of the medulla oblongata.

Nervous system.—The *olfactory nerves (fig.* 529*)* arise from the olfactory lobes of the brain,

* The various names applied by different authors to the different parts described above are calculated to create great embarrassment and confusion. Thus, Haller in his 'Physiology,' and likewise in his 'Opera Minora,' calls the lobes *(c, c) anterior olfactory tubercles*, the lobes *(e, e) inferior olfactory tubercles*, the hollow lobes *(b, b) optic thalamus*, &c. M. Arsaki, in his thesis 'De cerebro et medulla spinali piscium,' calls the hollow lobes *(b, b)* tubercula quadrigemina, and regards the anterior lobes *(c, c)* as the representatives of the hemispheres. M. Weber, in his 'Anatomia comparata nervi sympathetici,' whilst he recognizes the hollow lobes *(b, b)* as the cerebral hemispheres, regards the cerebellum *(a)* as the analogue of the tubercula quadrigemina, and the supplementary lobes *(g, g)* at the commencement of the medulla oblongata as representing the cerebellum.

and vary much in their size and composition in different Fishes. For the most part they are simple, but sometimes double or triple; and occasionally they are composed of numerous filaments united into fasciculi. Generally they present a ganglionic enlargement just after their origin from the brain, or immediately before their termination in the olfactory organ, to the plicated folds of the lined membrane of which they are ultimately distributed.

2. The *optic nerves (fig.* 529, 2*)* arise from the second pair of the great cerebral masses, which from this circumstance have been called the optic lobes of the brain. Shortly after their origin the two nerves cross each other, but in the generality of osseous Fishes this is effected without any union of substance, the two nerves being simply united by cellular tissue *(fig.* 528, *n).* In the Skates, however, a commissure exists similar to that which is met with in the higher Vertebrata. In some Fishes each optic nerve consists of a broad flat nervous band folded upon itself like a fan, and enclosed in a tube of neurilemma derived from the dura mater; but in others their structure resembles that which exists generally in the higher animals.

3. The *third pair* or *motor oculi (fig.* 529, 3) arises from the medulla oblongata in the track of the pyramidal bodies, and is distributed, as in other Vertebrata, to all the muscles of the eye, with the exception of the superior oblique and external rectus. It likewise furnishes ciliary nerves, but no ophthalmic ganglion has yet been discovered in the class before us.

4. The *fourth pair (fig.* 529, 4) arises just behind the posterior point of the optic lobe from the roof of the ventricle, and terminates in the superior oblique muscle of the eye.

5. The *fifth pair* of nerves *(fig.* 529, 5) arises from the sides of the fourth ventricle near the base of the cerebellum. It issues from the cranium through a foramen in the great alar bone, and is distributed as follows:—1. It gives off an *ophthalmic branch* which runs along the roof of the orbit, and passing on towards the nose is distributed to the adjacent parts of the face as far as the snout and intermaxillary bone. 2. A *superior maxillary branch*, which passes under the eye to be distributed to the cheek and to the superior maxilla; it likewise sends a branch towards the nostrils and anastomoses with the pterygo-palatine nerve. 3. An *inferior maxillary branch*, which is frequently only a division of the preceding: this gives filaments to the posterior part of the palate, and passes on to the inferior maxilla and its dental canal. Frequently the palatine filaments proceed from a special branch. 4. A *pterygo-palatine branch*, which runs forwards, crossing the floor of the orbit beneath the muscles of the eyeball, follows the course of the vomer, and passes beneath this bone and the os palati to terminate at the end of the muzzle, where it is frequently joined by remarkable anastomoses with the superior maxillary branch. 5. An *opercular branch*, which passes through a canal in the os temporale and gives branches to the temporal muscle,

Fig. 529.

Brain and cerebral nerves of Cod-fish (Gadus morrhua). (After Swan.)

a, olfactory lobes; *b*, hollow or cerebral lobes; *c*, cerebellum; *d*, medulla oblongata; *e*, olfactory apparatus; *f*, eye-ball; *g*, superior oblique muscle; *h*, external rectus; the numbers 1, 2, 3, 4, &c., indicate the corresponding cerebral nerves.

to the cheek, to the muscles of the operculum, and to the operculum itself; it then penetrates internally to join with branches of the inferior maxillary divisions and to supply filaments to the branchiostegous membrane. 6. The fifth pair almost invariably gives off a branch which mounts to the upper part of the cranium, and joining a branch of the eighth pair issues through a foramen formed by the parietal and interparietal bones, and runs along the whole length of the back on each side of the dorsal fins, receiving in its course filaments from all the spinal nerves, and giving off branches to the muscles and rays of the fins of the back. This branch is superficial up to the point where it plunges beneath the little external muscles of the fin-rays, and it sometimes gives off branches which are equally superficial, and that descend to the muscles of the trunk above the pectoral fins, and others which run backwards as far as the anal fin, where they form a longitudinal nerve resembling that of the back. Such is the general arrangement of this remarkable nerve, but it is by no means invariably so: thus, in the Carp it seems to proceed from the eighth pair, and not from the fifth. In the Silurus, on the contrary, it emanates from the fifth alone, while in the Perch, Cod, &c. it is derived, as has been described, equally from both these sources.

6. The *sixth pair* of nerves, or *abducens*, (*fig.* 529, 6) takes its origin, as in other Vertebrata, from the inferior surface of the medulla oblongata, and is entirely appropriated to the external rectus muscle of the eye.

7. The *seventh pair* of nerves (*fig.* 529, 7) is appropriated, as in other Vertebrata, to the sense of hearing. It arises from the medulla oblongata between the fifth and eighth pairs, and is distributed over the sacculi which contain the otolithes and the ampullæ connected with the semicircular canals of the ear. It has likewise connections with the last branch of the fifth pair, and one which is especially constant with the glosso-pharyngeal division of the eighth pair of nerves.

8. The roots forming the *eighth pair* (*fig.* 529, 8), or *nervus vagus*, are collectively almost as large as the fifth, behind which they take their origin generally by numerous filaments that issue in a single line, that runs longitudinally along the sides of the medulla oblongata beneath the lobes situated behind the cerebellum, and which unite into a ganglion (*fig.* 530, *t*) before its divisions are given off.

The distribution of the eighth pair of nerves in Fishes affords a striking example of the constancy with which a nerve presides over the same functions in every class of vertebrate animals.

The *glosso-pharyngeal* issues from the cranium sometimes through an aperture in the lateral occipital, sometimes through a foramen in the petrous bone, and supplies the first branchia and the parts in its immediate vicinity, whence it passes forward to the tongue, in which it is ultimately expended.

The *nervus vagus* properly so called leaves the cranium through a special foramen in the lateral occipital bone, and soon dilates into a large ganglion, from which nerves proceed to supply the three last branchiæ and the inferior parts of the pharynx. The trunk of the nerve then passes on along the pharynx and œsophagus as far as the stomach, which it likewise supplies. This distribution, as will be seen, is similar to what is found to exist in all the vertebrate classes as far as relates to the functions over which the nerve presides, although its arrangement is necessarily modified in consequence of the changed position of the respiratory organs. The eighth pair of nerves gives off one important branch, and sometimes two, the relations of which with what is met with in the superior classes are not so apparent. The first of these is a branch which arises sometimes from the anterior roots of the vagus, and sometimes from the posterior margin of its ganglion, and runs in a straight line as far as the tail. In many Fishes, after having given off a superficial filament which follows the commencement of the lateral line, the trunk of the nerve passes straight backwards imbedded in the thickness of the lateral muscles, between the ribs and their appendices, receiving special filaments from every one of the spinal nerves quite distinct from the intercostals, and giving off branches to the skin, which pass through all the intervals between the muscular layers. In other cases, as in the Cod-fish represented in the figure, it is superficial throughout its whole course, and apparently has no communication with the spinal nerves, although perhaps such communications may exist in the shape of very delicate fibrillæ.

The second remarkable branch is that already described as joining an offset from the fifth to form the dorsal nerve.

The eighth pair likewise gives off filaments to the diaphragm or membranous septum which divides the branchial chamber from the abdominal cavity.

The last pair of cranial nerves arises behind the eighth pair from the medulla oblongata, and, after giving a branch to the swimming bladder, is distributed to the muscles of the shoulder, and those which pass between the shoulder and the hyoid apparatus; it also gives branches which anastomose with those of the first spinal nerve, and from the plexus thus formed the nerves proceed which supply the external and anterior muscles of the pectoral fins.

The second pair of spinal nerves supply the internal and posterior muscles of the pectoral fins. In the Triglæ (*Gurnards*) these nerves are remarkable for their great size, and on account of the large branches that they give off to the free rays situated in front of the pectorals. They arise from the sides of the last of the five pairs of post-cerebellic lobes, which in this race of Fishes are so remarkable.

In Fishes which have their pelvis suspended to the bones of the shoulder, whether the ventral fins appear in front of the pectorals or beneath them, or behind them, it is from the third and fourth pairs of spinal nerves that the ventrals receive their supply; the third specially supplying the muscles of the pelvis, to which likewise the fourth give some branches, but the latter is more particularly distributed to the fin-rays. The muscles of this fin likewise derive some filaments from the fifth pair of spinal nerves.

In the jugular division of Malacopteryginous Fishes, in which the ventral fins are attached

Fig. 530.

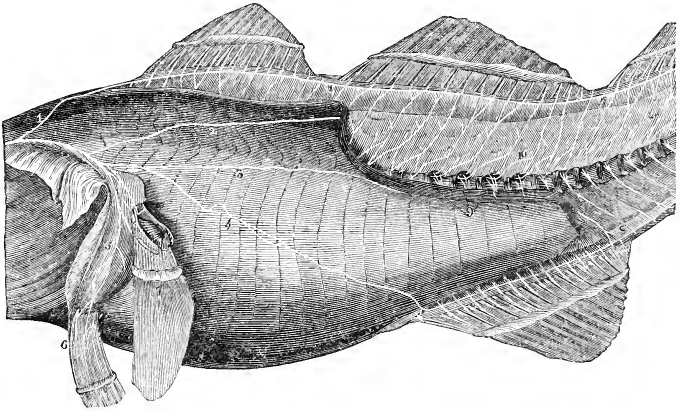
s, s, vestibule of the ear; other letters as in *figs.* 526, 527, and 528. (After Cuvier.)

beneath the throat in front of the pectorals, they are supplied from the same pairs of nerves; but in the abdominal division, where the ventrals are situated towards the hinder part of the body, they receive their supply from spinal nerves placed proportionally further back.

Sympathetic system.—The sympathetic system of nerves is in Fishes extremely small, so much so, indeed, that its existence has been denied by some anatomists; it is, however, invariably present, although its filaments are of great tenuity. It runs along the sides of the

Fig. 531.



Lateral and spinal nerves of the Cod (Gadus morrhua). (After Swan.)

1, 1, 1, dorsal communicating branch, derived from the fifth pair and nervus vagus, which joins all the nerves of the dorsal fins 10; 2 and 3, two branches from the trunk of the par vagum passing down along the side underneath the skin; 4, branch running beneath the skin, which communicates with the inferior branches of the spinal nerves; 8, 9, exit of the nerves from the spinal canal.

spine, as in the higher Vertebrata, receiving branches from each of the spinal nerves, and anteriorly it communicates with a branch of the fifth, and also with the nervus vagus. On the left side, after having sent a filament to join the trunk of the par vagum on the stomach,* it

* Swan, Comp. Anat. of Nerv. Syst. p. 24.

sends a branch across to join its fellow on the right side in the splanchnic nerve. This forms a ganglionic enlargement on the mesenteric artery, and, after communicating with the right trunk of the par vagum, terminates on the intestines and other viscera. On each side of the aorta the prolongation of the sympathetic is continued down to the tail, giving filaments to the lateral branches proceeding from the aorta, and communicating with the spinal nerves. Near the anus filaments are sent off, which unite and accompany the spermatic artery to the ovaries.

According to the united testimony of Costa, Rathke, and Goodsir, no vestige of a brain or encephalic enlargement of the medulla spinalis is visible in Branchiostoma, a fact of extreme interest to the physiologist. In these extraordinary Fishes, the spinal cord, as described by the last mentioned gentleman, stretches along the whole length of the spine, is acuminated at both ends, and exhibits not the slightest trace of cerebral developement. It is most developed in its middle third, where it has the form of a riband, the thickness of which is about one-fourth or one-fifth of its breadth; and along this portion also it presents on its upper surface a broad but shallow groove. The other two-thirds are not so flat, and are not grooved above. They taper off gradually, the one towards the anterior, the other towards the posterior end of the Fish.

From fifty-five to sixty nerves pass off from each side of the cord; but as the anterior and posterior vertebræ are very minute and run into one another, and as the spinal cord itself almost disappears at the two extremities, it is impossible to ascertain the exact number either of vertebræ or spinal nerves. These nerves, Mr. Goodsir assures us, are not connected to the spinal marrow by double roots, but are inserted into its edges in the form of simple cords.

The nerves pass out of the intervertebral foramina of the membranous spinal canal, divide into two sets of branches, one set (dorsal branches) running up between the dorsal muscular bundles; the others (ventral branches) run obliquely downwards and backwards on the surface of the fibrous sheath of the vertebral column, and are distributed to the muscles of the ventral region.

When an entire animal is examined by transmitted light and a sufficient magnifying power, the anterior extremity of the spinal cord is observed, as before mentioned, to terminate in a minute filament above the anterior extremity of the vertebral column. The first pair of nerves is excessively minute, and passes to the parts around the mouth. The second pair is considerably larger; it sends a considerable branch, corresponding to the dorsal branches of the other nerves, passes upwards and backwards along the anterior edge of the first dorsal muscular bundle. This branch joins the dorsal branches of the third and of a considerable number of the succeeding pairs of nerves, at last becoming too minute to be traced further.

After sending off this dorsal branch the second pair passes downwards and backwards on each edge above the hyoid apparatus, and joins all the ventral branches of the other spinal nerves in succession, as its dorsal branch did along the back. This ventral branch of the second pair is very conspicuous and may be traced beyond the anus, but is lost sight of near the extremity of the tail; it evidently corresponds with the nerve represented in *fig.* 531, 1, as the dorsal communicating branch does with the nerve marked 4 in the same figure.

Sense of smell.—In the structure of their olfactory apparatus Fishes present a remarkable difference from all other vertebrate animals; their nostrils are in fact quite unconnected with the respiratory passages, consisting of mere sacculi, into which the surrounding water obtains free access, which are lined with a pituitary membrane folded into regular plicæ, so as to offer an extensive surface for contact. Their usual situation is towards the fore part of the face, where they are supported by the *vomer*, the *maxillary*, and the *intermaxillary* bones, the first *suborbital* bounding their lower margin, while above they are arched over by a bone distinguished by Cuvier as the *nasal*.

The openings of the nostrils are of a round, oval, or oblong shape; they are situated either at the end of the muzzle or upon its sides, or upon its upper surface, or sometimes even beneath, as in the Rays and Sharks, where they are found near the angles of the mouth. In the Lamprey they are placed quite at the summit of the head, and open by a common orifice; but in the greater number of Fishes, perhaps in all the osseous races, each olfactory sacculus presents two orifices, one in front, the other behind, which are sometimes sufficiently remote from each other, but both orifices open into the same cavity.

The anterior orifice sometimes has its edges tubular, as in the Eel, and sometimes this tubular edge is prolonged, as in the Lote and some of the Siluridæ, into a tentacle of more or less considerable length: at other times these tubular prolongations are wanting, as in the Scombridæ, in which family, moreover, the posterior nostrils are but vertical slits.

The nostrils of the Lophius offer a remarkable peculiarity, each being supported upon a little pedicle so as to resemble a mushroom, the expansion of the mushroom containing the olfactory cavity, which, as usual, communicates with the exterior by two little orifices.

In some rare instances the posterior aperture of the olfactory sacculus is situated beneath the lip, a circumstance which is more especially remarkable in some foreign Congers, and exhibits a remarkable approximation to what is met with in the amphibious *Proteus* and *Siren.*

The disposition of the pituitary membrane that lines the nasal sacculus is very simple; where the shape of the olfactory cavity is round, the folds of the membrane which lines it are disposed like the radii of a circle (*fig.* 529); but if the nasal fossæ are oblong or elongated, they are arranged along the two sides of an axis in very regular folds, resembling in their arrangement the barbs of a feather. In the number and prominency of these folds there is great variety. In the Lump-fish *(Cyclopterus)* they are hardly perceptible; in the Perch there are only sixteen in each nasal sac, and in the Turbot twenty-four, whilst in the Conger or the Eel their number is prodigious, seeing that they extend along the entire length of the long tubular nostril. The rays themselves divide into secondary folds in the Sturgeon, and perhaps in other species; in short, various modes of plication are adopted in different races, but the object obtained is the same in all cases, namely, an extension of the surface of the olfactory membrane. This surface exhibits numerous delicate vessels, and secretes an abundant mucosity which lubricates its interior.

The olfactory nerve, at its commencement from the anterior tubercles of the brain, is sometimes single, sometimes double, and sometimes divided into many filaments of variable number, length, and thickness in different genera, which pass to the posterior or convex aspect of the olfactory sacculus. In its course and distribution differences are likewise observable. Thus, in some genera, as the Tetradons, it is exceedingly slender; in others, as in the Cod (*fig.* 529), it is likewise of great tenuity, but double or triple. The Rays and Sharks have it thick and single, and in these races it is sometimes so short as absolutely to appear merely an appendage of the brain. In the Tunny likewise it is simple throughout its whole length. In the Perch, about the middle of its course it divides into two, and its divisions become multiplied as it approaches the nose. In the Conger and Eel it is divided almost from its origin into two large trunks, each of which gives off successively a great number of branches, which subdivide into ramuscules to be distributed to all the lamellæ of their long nostril.

In many genera of Fishes the olfactory nerve, at the point where it reaches the nasal cavity, dilates into a ganglion, as may be seen in the Cod-fish, the Carp, and the Cyprinidæ generally; and, lastly, the terminal olfactory filaments penetrate into all the folds of the pituitary membrane, and terminate at their free margins.

It does not appear, at least in the osseous Fishes, that the coverings of the nasal cavities or that their openings have any muscles calculated to contract or to expand them.

Eye.—The eye-ball of Fishes presents many peculiarities of structure which are rendered necessary by their habits for the purpose of retaining the flattened figure of the cornea, and of meeting other circumstances of the condition under which aquatic vision has to be performed.

The sclerotic coat which gives shape to the entire eye-ball is a dense and fibrous investment enclosing the whole eye, except anteriorly, where a space is left for the transparent cornea. Its thickness varies in different parts to a greater extent than in any other class of vertebrate animals, being generally greatest at the posterior part of the eye, so as to preserve the cup-shaped form of the eye. In the Sturgeon, for example, its thickness in this region is prodigious, and in the Cod-fish and Shark the same circumstance is remarkable, although in a less degree. Still further to secure the requisite form of the eye strong plates of cartilage are very frequently developed in the substance of the sclerotic, generally at the back of the eye, but sometimes round the cornea likewise, which in the larger Fishes occasionally become ossified, of which a notable example is met with in the Sword-fish *(Xiphias)*, where the ossified portion of the sclerotic forms a bony cup of a spherical form surrounding the entire globe of the eye, except opposite the cornea, and where the aperture is left for the entrance of the optic nerve.

In the Rays and Sharks among the Chondropterygii, the sclerotic, which is of a cartilaginous texture, presents another peculiarity in the presence of a prominent tubercle, which projects externally to be moveably articulated with a pedicle of cartilage derived from the back of the orbit, which thus forms a pivot or centre for the movements of the eyeball. The proper cornea is an exceedingly thin laminated membrane, filling up the anterior opening of the sclerotic; its thickness, however, is considerably increased by the external integument, which passes over it externally under the name of *membrana conjunctiva:* in some species indeed, as Cecilia and Gastrobranchus, such is the opacity of this tegumentary membrane that all vision is precluded. Immediately beneath the sclerotic there is generally a large quantity of fatty cellular membrane; this is, however, sometimes wanting, but occasionally, as for example in the Moon-fish *(Orthagoriscus Mola)*, its thickness is very considerable.

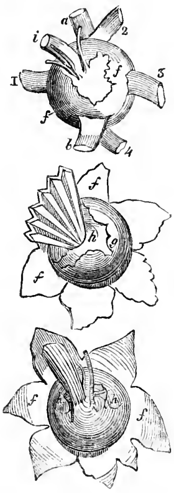
On removing this cellular investment a delicate membrane presents itself, of a brilliant metallic lustre *(membrana argentea)*, which indeed from its softness resembles rather a layer of pigment than a true tunic of the eyeball. It is this layer which spreads anteriorly over the front of the iris, giving it the metallic brilliancy for which in Fishes it is so remarkable.

The iris itself is formed as in other Vertebrata, but the pupil generally remains fixed and motionless; the most remarkable peculiarities noticeable in this part of the eye having reference to the shape of the pupil, which is very various in its form. Thus in the Grey Shark *(Galeus communis)* it is quadrangular; in the Rays and Pleuronectidæ the pupillary aperture is closed by a kind of palmate membrane, which hangs down like a curtain from its upper border; while in one singular case, the Anableps, there is a double pupil as well as a double cornea, although in all other particulars the structure of the eye agrees with that of ordinary Fishes.

The *choroid* of Fishes presents no peculiarity of structure worthy of notice; it is very vascular and deeply stained with black or dark-coloured pigment. As in the higher animals, it is separable into two layers: the outer or true choroid, which is properly the vascular layer, is of considerable thickness, while the inner layer forms the *tunica Ruyschiana.* This latter tunic, as it approaches the margin of the iris, is gathered into numerous beautiful radiating folds *(ciliary plicæ)*; these in very large eyes, as in the Moon-fish *(Orthagoriscus)* for example, are seen each of them to consist of two or three minute folds, which, as they run forwards, unite into one and terminate in a point at the circumference of the iris, but in no instance do they project freely inwards as distinct processes, so as to resemble the ciliary processes of Mammiferous Vertebrata. The ciliary plicæ, as indeed most of the posterior surface of the iris, is in immediate contact with the membrane of the vitreous humour, to which it is intimately adherent; for in Fishes there is no posterior chamber of the aqueous humour, the anterior segment of the crystalline lens projecting in many instances quite through the pupillary aperture.

In a space enclosed between the proper choroid and the membrana argentea is a structure quite peculiar to the osseous Fishes, for it is not met with even in the Chondropterygious races.* This consists of a spongy mass of irregular form, which partially surrounds the entrance of the optic nerve (*fig.* 532, *h*), and extends for some distance towards the front

Fig. 532.



Coats of the eye of the Perch. (After Cuvier.)

Fig. 1, muscles of eye-ball; *a*, superior oblique; *b*, inferior oblique; 1, 2, 3, 4, recti muscles; *i*, optic nerve. Figs. 2 and 3, *f*, *f*, *f*, fatty matter; *g*, choroid; *h*, "choroid gland."

of the eyeball. This body, which has been absurdly called the *choroid gland*, is sometimes divided into two portions; at others it assumes a somewhat crescentic form, but it is always deficient towards the lower part of the eye. Its colour is always a deep red, and its tissue is principally made up of bloodvessels running transversely in close parallel lines. Other vessels issue from it which are frequently very tortuous and always much ramified; these run into the choroid, where they form so dense a network that it was described by Haller as a distinct membrane, and has been subsequently named *membrana Halleri*. The use of the so-called choroid gland has not been fully ascertained; most probably, however, it is essentially composed of erectile tissue, which by its dilatation and contraction may have some influence in accommodating the form of the eye to the distance of objects, or the varying density of the medium through which they are seen.

The optic nerve in many Fishes (at least among the Acanthopterygii) is made up of a broad layer of nervous matter folded upon itself like a fan (*fig.* 532) and enclosed in a fibrous envelope, which is continuous with the sclerotic coat of the eye. The nerve enters the eye at a point remote from the axis of vision, penetrating for the most part by an oblique course, so that after having pierced the sclerotic it has still a considerable distance to pass through the substratum of cellular tissue and between the masses of the "choroid gland" before it pierces the choroid and Ruyschian tunics. Its diameter is much diminished at the point where it shews itself in the interior of the eye, where it appears sometimes as a mere point, at others under the form of a round or irregular spot, or sometimes represents a straight line. It then expands into the retina, which, when the nerve is folded, as above described, has likewise a plicated appearance. The retina, as in other Vertebrata, lines all the internal cavity of the eye as far as the ciliary plicæ, thus enveloping the vitreous humour.

Another peculiarity in the structure of the Fish's eye is the existence of an apparatus apparently analogous to the marsupium of Birds, which extends from the choroid to the back of the lens, passing quite through the vitreous humour, to which the name of *falciform ligament* has been given. This structure arises by a broad origin from the inner surface of the choroid at the back part of the eye, and extending forwards, following the concavity of the eyeball along its lower surface, arrives at the ciliary zone and is connected with the back of the capsule of the lens. Its shape is falciform, as the name indicates, the convexity of the curve being attached along the floor of the interior of the eye. In the recent eye it is a delicate and almost imperceptible membrane, but maceration in spirit by rendering it opaque reveals it to consist of several layers of cellulosity, most probably enclosing numerous vessels. According to Cuvier and the younger Soemmering,* the falciform ligament passes through the retina, which is fissured to let it through; but an examination of the large eyes of the Moon-fish after long immersion in spirit

* Cuvier et Valenciennes, Hist. Nat. des Poissons, tom. i. p. 337.

* De oculorum hominis animaliumque sectione horizontali commentatio. Fol. Goettingæ, 1818.

distinctly shews the plicated retina continued on to the surface of the ligament, which seems to be covered with the nervous expansion.*

Humours of the eye.—The quantity of the aqueous humour in a Fish's eye is comparatively very small, owing to the flat shape of the cornea and the almost perfect immobility of the iris. The posterior chamber is, indeed, quite deficient, the uvea of the iris being adherent to the capsule of the vitreous humour; and even the anterior chamber is frequently materially encroached upon by the protrusion of the crystalline lens through the aperture of the pupil. As a refracting medium it is evident that the aqueous humour, being nearly of the same density as the surrounding medium, could have little effect in concentrating luminous rays, this duty being principally assigned to the powerful lens immediately behind it.

The crystalline lens in Fishes is nearly of a spherical form, thus presenting the converse as regards its refractive power of what exists in the eye of Birds. The size of the lens in these aquatic animals is very great, so that it encroaches largely upon the chamber of the vitreous humour, extending to more than half way between the pupil and the back of the cavity of the eyeball. Its consistence is very great, and its nucleus so hard as to remain transparent even after immersion in spirit of wine. It is enclosed in a soft capsule, between which and the surface of the crystalline lens is a small quantity of fluid, and is fixed in a deep depression in the fore part of the vitreous humour by a circular membranous zone derived from the hyaloid tunic, which surrounds it like the artificial horizon of a geographical globe. Sir David Brewster, in an admirable paper on the anatomical and optical structure of the crystalline lens,† gives the following interesting particulars relative to its minute organization in the class of Fishes. Its form is that of a prolate spheroid, the axis of revolution being a little longer than the equatorial diameter. This axis is the axis of the eye or of vision. The body or substance of the lens is enclosed in an exceedingly thin and transparent membrane, called its capsule; and if this be punctured, a thickish fluid flows from the opening; but upon removing the capsule altogether, this fluid is found to constitute only the outer coat of the lens, the substance of the lens growing denser and harder as we approach the centre of it.

The body of the lens is not connected with the capsule by any nerves or filaments whatever; on the contrary, it floats as it were within the capsule, and on holding the lens in his hand, Sir D. Brewster observed its axis of revolution take a horizontal position whenever it was placed in an inclined direction. This was repeated several times with the same lens, although the experiment was tried unsuccessfully with others. When the lens is taken out of its capsule, and the softer parts removed by rubbing it between the finger and thumb, a hard nucleus is obtained, which consists of regular transparent laminæ of uniform thickness, and capable of being separated like those of sulphate of lime or mica.

When the surface of any lamina has been examined before it has been detached, it has the appearance of a grooved surface like mother-of-pearl; and in large lenses it is often easy to trace these apparent grooves or lines to the two poles of the axis of revolution, the fibres bounded by them being consequently widest at the equator, and growing narrower and narrower as they approach the poles. The maximum breadth of these fibres is about the 5500dth part of an inch, but of course they become gradually attenuated as they approach the poles of the lens in either direction.

Having thus determined the form and size of the fibres which enter into the composition of the crystalline lens, it remained to ascertain the mode in which they were fastened together so as to resist separation and form a continuous spherical surface, and this was found to be effected by a very curious mechanism, the contiguous fibres being united by means of teeth exactly like those of rack-work, the projecting teeth of one fibre entering into the hollows between the teeth of the adjacent one. It was further found that the fibres gradually diminish in size towards the centre of the lens, and the teeth in the same proportion, so that the number of fibres in any spherical coat or lamina was the same from whatever part of the lens it it was detached. In conclusion, Sir David Brewster observes, "In the lens of a Cod I found that there were 2000 fibres in an inch at the equator of a spherical coat or lamina, whose radius was $\frac{6}{30}$ths of an inch; consequently there must have been 2500 in the spherical surface. If we now suppose that the breadth of each fibre is five times its thickness, and that each tooth is equal to the thickness of the fibre, or that five teeth are equal in breadth to a fibre, we shall obtain the following results for the lens of a Cod four-tenths of an inch in diameter:—

Number of fibres in each lamina or spherical coat . .	2,500
Number of teeth in each fibre	12,000
Number of teeth in each spherical coat	31,250,000
Number of fibres in the lens .	5,000,000
Number of teeth in the lens .	62,500,000,000

or, to express the result in words, the lens of a small Cod contains five millions of fibres and sixty-two thousand five hundred millions of teeth. A transparent lens exhibiting such a mechanism may well excite our astonishment and admiration."

The *vitreous humour* in Fishes is proportionally less abundant than in other races of Vertebrata,—a circumstance which is partly owing to the shortness of the antero-posterior diameter of the chamber of the eye-ball, and partly to the extent to which it is encroached upon by the large spherical crystalline lens; in other respects it presents no peculiarities worthy of special description.

Muscles of the eyeball. — The eyeball of

* Vide Preparation 1650, in the physiological series of the Museum of the Royal College of Surgeons, London.

† Phil. Transact. for 1833, p. 323.

Fishes is moved by six muscles analogous to those met with in other Vertebrata, and to which similar names are applicable. The *recti* muscles (*fig.* 532, 1, 2, 3, 4) are four in number, arising from the back of the orbit near the margin of the optic groove, and running forward to be attached in the usual manner to the sclerotic coat of the eye. The *obliqui* (*fig.* 532, *a*, *b*) both take their origin from the anterior part of the walls of the orbit, and pass in a transverse direction towards the eyeball, into which they are inserted, one on its superior, the other on its inferior aspect. There is no trochlear apparatus in connection with the superior oblique, as is the case in quadrupeds, but, like the inferior, it passes straight to its destination. The suspensory or choanoid muscle met with in Mammalia, in Fishes is totally wanting.

In the Sharks the muscles moving the eyeball are of very great strength, and, moreover, their efficiency is rendered more perfect by mechanical contrivances that are not met with in the ordinary Fishes. In the latter the eye is simply supported in the orbit by a quantity of loose cellulosity filled with a gelatinous or fatty semifluid substance, admirably adapted to facilitate the movements of the eye; but in the plagiostome cartilaginous Fishes the cartilaginous pedicle is provided, already mentioned, which, taking its origin from the back of the orbit between the origins of the recti muscles, runs forward to be moveably articulated, frequently by means of a very complete ball-and-socket joint enclosed in a capsular ligament, to the back of the selerotic, so as to form a pivot upon which the eye turns. In the attachment of the recti and oblique muscles to the eye-ball an additional piece of mechanism is observable, each of these muscles being inserted into a prominent cartilaginous tubercle, which projects from the external surface of the sclerotic, and thus enables the muscle to act with greater advantage.

In the generality of Fishes there are no eyelids, the external tegument passing on to the front of the eye-ball without forming any fold or duplicature to which such a title is applicable; there are, however, exceptions to this arrangement which must not be passed over unnoticed. Thus, in the Mackarel (*Scomber Scombrus*), the eye is partially defended by two vertical folds of the common integument, and in the Herring (*Clupea Harengus*) there is a similar provision for the defence of the eye-ball and orbit.* The vertical folds are unprovided with any muscular structure for their movement, and are consequently transparent so as not to interfere with vision when the front of the eye is brought beneath them. It is worthy of observation that, where these folds decussate one another at their inferior extremities, the anterior one overlaps the posterior, so slight an impediment to progressive motion as the contrary position would have occasioned having thus been foreseen and avoided.

In the Sharks and Sturgeons the integument forms a deep circular fold around the front of the eye, which, although motionless, is evidently of a palpebral character. A secreting *membrana conjunctiva* is reflected deeply between this circular fold and the globe of the eye, of which it covers the anterior half. In the Sharks* there is likewise a third eyelid, which is moveable; this is placed at the inferior and internal or nasal side of the orbit, and is moved over the front of the eye in a direction upwards and outwards by means of a strong round muscle (*nictitator*) which arises from the upper and posterior or temporal side of the orbit, and descends obliquely to be inserted into the lower and outer margin of the third eye-lid; passing in this course first through a muscular trochlea, and then through a ligamento-cartilaginous loop. The trochlear muscle is not, however, exclusively subservient to the action of the nictitator, but has an insertion in the upper part of the palpebral fold, which it depresses simultaneously with the raising of the third eyelid, a slight external groove above the upper eyelid indicating the extent of motion allowed.

The lacrymal apparatus is totally wanting in the whole race of Fises, no trace of lacrymal glands or punctæ lacrymaliæ being ever distinguishable; neither could a lacrymal secretion be needed in animals whose eyes are perpetually bathed by the water in which they live.

Auditory apparatus.—The organ of hearing in Fishes undergoes a gradual improvement in its structure as we advance from the lower to the more highly organized genera, presenting almost every intermediate gradation between the least complex form, in which it consists of the vestibule alone, without semicircular canals or other appendages, approximating in simplicity the ear of a Cuttle-fish (vide art. CEPHALOPODA), to the most complete icthyic type of the auditory apparatus, met with in the Sharks and Sturgeons.

It is in the Lampreys (*Petromyzon*) that the auditory organ exists in its humblest state of developement.† In these Fishes the ear is enclosed in a simple cartilaginous capsule of an elliptical figure, situated on each side of the skull external to the posterior cranial cartilages. The walls of these capsules are thin, and the cavity which they contain of an ovoid shape. In that side of each cartilaginous capsule (vestibulum cartilagineum, *Weber,*) which is nearest the cranium, are two openings, the inferior, which is the larger, being of an oval shape closed with a firm and elastic membrane, while the superior is extremely small, giving transit to the auditory nerve as it passes into the vestibule. With the exception of these apertures, which open into the cavity of the cranium, the cartilaginous capsule is closed on all sides.

The whole of the elliptical cavity of the cartilaginous capsule is filled by a pellucid membranous sac (*vestibulum membranaceum*)

* Vide Catalogue, Mus. Coll. Surgeons, Lond. vol. iii. p. 171.

* Catalogue, Mus. Coll. Surgeons. Lond. prep. 1762.

† Vide Tract. de Aure animalium aquatilium, auctore Ernesto Henrico Webero. Lipsiæ, 1820. 4to.

turgidly filled with a transparent fluid; the membranous vestibule, however, does not adhere to the walls of the capsule except at the orifices leading into the cranium. The membranous vestibule has its cavity divided into several compartments by folds projecting into its interior, and receives the auditory nerve, which being changed into a pulpy mass spreads out over its walls.

In the Petromyzonidæ therefore three important parts of the auditory apparatus, which are met with in the ear of all other Fishes, are wanting, viz. the sac of the *otolithe*, the *otolithe* itself, and the *semicircular canals*, except indeed rudiments of the latter may be represented by two curved folds of the membrane of the vestibule, which are joined superiorly to a similar fold, an arrangement which is met with both in the river and sea-lamprey. The auditory nerve is derived immediately from the brain.

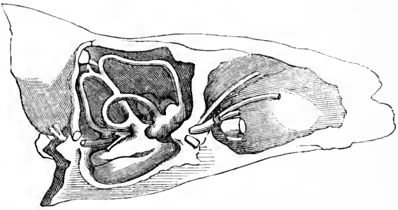
From the above description it would appear that in the Lampreys there are two modes whereby sonorous vibrations may be communicated to the vestibule, one through the cartilaginous capsule of the ear, the other through the cranium, which communicating tremors impressed upon it from without to the fluid which is contained in its cavity, the vibration reaches the tense membrane that closes the large fenestra leading to the vestibule, and thus affects the membranous vestibular sac itself.

In a second group Weber includes those forms of the ear which have no cartilaginous or osseous vestibule separate from the cranial cavity. This kind of ear exists in by far the greater number of Fishes, being met with in all the truly osseous and branchiostegous races as well as in some Chondropterygians; in none of which is the membranous labyrinth enclosed in a bony or cartilaginous envelope, the internal ear being contained in the cavity of the skull itself near the posterior part of the cerebrum, with which, in fact, it is for the most part in apposition; for in these Fishes the cranium being very large and having only a small part of its cavity occupied by the brain itself, performs the office of an osseous labyrinth, not only by furnishing a receptacle to the internal ear in which every part necessary to the performance of its functions may be fitly suspended, but is filled with fluid with which the membranous labyrinth is every where surrounded, a provision not less necessary to the sense of hearing than is the fluid contained in the interior of the vestibule and semicircular canals. In all such Fishes, therefore, the auditory apparatus, consisting of a membranous vestibule and semicircular canals, is lodged on each side in cavities excavated in the base of the cranium and bounded by the temporal and lateral parts of the occipital bones.

The internal ear itself (*fig.* 528) is composed of the following parts: 1st. The membranous vestibule (*fig.* 525, *i*). 2d. The sac of the otolithe. 3d. The membranous semicircular canals.

The membranous vestibule is an elongated smooth sacculus of very various form in different Fishes. Its parietes consist of a pellucid membrane, and its outer surface is connected by loose cellular tissue to the sides of the cavity in which it is lodged. Its anterior extremity is somewhat dilated and contains a little otolithe; moreover into it open the ampullæ of the anterior and external semi-

Fig. 533.



Internal ear of Perch. (After Cuvier.)

circular canals. The posterior extremity of the vestibule is narrower, and into this part opens the ampulla of the posterior semicircular canal and the hinder termination of the external one. Near the middle of the vestibular sac enters the wide duct formed by the conjunction of the terminations of the anterior and posterior semicircular canals; but whether this wide duct ought rather to be looked upon as forming part of the vestibule or of the semicircular canals may be a matter of doubt, although the latter supposition is the most probable.

Thus the six extremities of the three semicircular canals communicate with the cavity of the membranous vestibule, not by six, but by five orifices.

The membrane of which the vestibule consists is considerably thinner than that which forms the semicircular canals; indeed it is so delicate that if torn it at once collapses and is scarcely distinguishable from the surrounding parts.

In the Pike (*Esox lucius*) there is a remarkable appendage to the vestibule which is not met with in other Fishes. This consists of a pyriform membranous sacculus lodged in the commencement of the spinal canal, which opens into the vestibular cavity by a narrow orifice near the entrance of the posterior semicircular canal. The thickness of the walls of this sacculus is much greater than that of the parietes of the vestibule, resembling rather in this respect the ampullæ of the semicircular canals. Some of the upper spinal nerves are distributed to this organ, but they give off no branches, nor does it appear to receive any filament from the auditory nerve.

The *sac of the otolithe* in most Fishes is immediately beneath and in close contact with the membranous vestibule, but in some it is hidden in the base of the occipital bone more remote from the vestibular cavity, with which it is joined by a narrower duct. The *saccus* is most generally divided into two portions by a median septum, in such a way, however, that the anterior is much the larger compartment, to which the posterior chamber seems a superadded appendix. Both of these compartments are filled with a pellucid fluid, and each contains a stony mass or *otolithe*, of which that in the anterior is the largest, that in the posterior being comparatively of small dimensions. In *Orthagoriscus*, however, according to Cuvier, the saccus is single, and instead of an *otolithe* only contains a few granules apparently rather of mucus than of cretaceous substance.

Otolithes.—Most Fishes are furnished with three stony masses, which are intimately connected with the function of hearing. Of these, the *otolithes* or *lapilli*, one, generally the smallest, is contained in the anterior extremity of the vestibule; the other two are situated in the two compartments of the *saccus*. The otolithe contained in the anterior compartment of the *saccus* is generally of remarkable size, forming a considerable protuberance in the base of the occipital bone, in which it is lodged; this is conspicuously seen in the Gadidæ and some of the Perch tribe.

The substance of these otolithes consists of carbonate of lime, but they assume various degrees of hardness and considerable diversity of colour in different Fishes. In most cases they present a texture as hard and fragile as porcelain. In a few instances, as for example in the Sturgeon (*Accipenser Sturio*), there is only one lapillus, which is soft and as easily crushed and reduced to powder as a piece of chalk; as is likewise the case with the otolithes of the *Raidæ* and *Squalidæ*.

In shape the otolithes vary exceedingly in different genera. For the most part they are smooth and present this character in common, that they are marked with asperities, fossæ, and grooves for the attachment or reception of nervous filaments. Those contained in the *saccus* are frequently surrounded by a serrated margin, which is rarely the case with the lapilli of the vestibule. But whilst there is so much diversity in the shape of the otolithes belonging to different genera of Fishes, the form of those met with in the species belonging to the same genus is wonderfully constant, so much so, indeed, that not only the general outline, but the most minute fossules and grooves were found by Weber accurately to correspond in different specimens, so that it was difficult to distinguish one from the other; from which circumstance those otolithes might be employed with advantage as affording excellent generic characters to the zoologist. The connection of the otolithes with the saccus or with the vestibule is so difficult to be perceived, that they might be thought to be loose in the contained fluid; when, however, we find them small in the younger Fishes, and increasing in size as age advances, it is evident that they must receive nutritious vessels; they are moreover attached by nervous filaments of extreme delicacy, which pass to them from the saccus. In many points they touch the membranous walls of the cavity in which they are lodged; when, therefore, the sac is but loosely connected with the bones of the cranium, sonorous vibrations cannot be communicated immediately from the cranium to the lapilli, but must first be communicated to the surrounding fluid.

Semicircular canals.—All Fishes, with the exception of the Petromyzonidæ, have three semicircular canals entering into the formation of the internal organ of hearing, and the arrangement of which is as follows. The *anterior* arises by one extremity from the anterior part of the vestibule, and, winding upwards and backwards, meets the posterior semicircular canal derived from the hinder part of the vestibular cavity; at the point of meeting the two join to form one common duct, which enters the vestibule near its middle. Both these canals are placed perpendicularly. The third or external semicircular canal issues from the anterior part of the vestibule, and winds horizontally outwards to join the vestibule again at its posterior part near the origin of the *posterior* canal. In this way the three semicircular canals open into the membranous vestibule by five orifices. In the Herring, however, (*Clupea Harengus*) not only do the anterior and posterior canals unite, but the external also joins the posterior, so that in this fish there are only four apertures communicating with the vestibule.

Each of the semicircular canals near its commencement from the vestibule swells into an oval dilatation called the *ampulla*, so that three of these ampullæ exist, two at the anterior part of the vestibule, and the third near its posterior extremity.

The connection between the semicircular canals and the cranium is effected by the assistance of osseous passages, in which one or two (rarely all three) of the semicircular canals are lodged, and in some Fishes, as for example in Cobitis fossilis, these are entirely deficient. The membranous canals are not at all adherent to the osseous passages, but are only connected with them by the intervention of a most delicate cellulosity, or are merely suspended in a fluid, with which all the osseous canals as well as the entire cranium is filled up; they are consequently extracted without the employment of the slightest force.

Those canals which are not enclosed in bony channels are simply annexed to the bones of the cranium by a fine cellular web.

From the above arrangement it may be clearly understood that these parts are purposely left but loosely connected to the surface of the bones, for otherwise the bony canals would not so greatly exceed the membranous ones in size, but on the contrary would be filled and lined by them throughout; and that sonorous vibrations most readily arrive at the labyrinth through the fluid with which the canals are surrounded.

In *Muræna anguilla* the anterior and posterior semicircular canals mount so high towards the vertex of the cranium that they are not placed by the side of the brain, but absolutely rise above it and approximate their fellows of the opposite side.

The length and calibre of the semicircular canals vary very much, not only in different species, but also when compared with each other.

The tissue of which they are composed is similar to that which forms the membranous vestibule and *saccus;* it is, however, a tissue sui generis, being neither exactly comparable to cartilage, nor tendon, nor cellular membrane. It is pellucid, and when emptied of the enclosed fluid, inelastic, but flexible and easily torn. Its thickness is greater than that of the vestibule or of the sac of the otolithe; but the ampullæ seem thicker than the rest, for when wounded and their contents allowed to escape they still retain their form and expansion.

The membranous labyrinth is filled with a limpid fluid.

Auditory nerves.—The labyrinth of the ear in Fishes receives its nerves from two sources,* 1st, from the auditory nerve, properly so called, which is distributed to the membranous vestibule, and to the ampullæ of the anterior and external semicircular canals; 2ndly, from the "accessory auditory nerve," which, in most instances, seems to arise not from the brain but from the trigeminal or the vagus nerve, and supplies the ampulla of the posterior semicircular canal and the *saccus.*

Ear of plagiostome cartilaginous Fishes.—In the Skate are two canals, regarded by Monro as representing the meatus auditorius externus. The orifices of these are situated at the upper and back part of the head at a short distance from the junction of the skull with the first cervical vertebra, the opening of each being large enough to admit the end of a probe. Each of these orifices leads to a winding canal about two lines in diameter, which, after describing more than three-fourths of a circle, may be traced into the membranous vestibule of the ear. This canal is generally found filled with a white viscid matter. The vestibule is a large sac containing a very viscid pellucid humour, in consistence like the white of an egg, in which is suspended a soft cretaceous substance. To the anterior part of the large sac there is a smaller compartment communicating with the former by a narrow passage, which is likewise filled with glairy fluid, and, posteriorly, there is a third very small sacculus, similarly distended, in both of which cretaceous matter is found.

The remaining portion of the internal ear consists of three canals, analogous to the semicircular canals of the higher Vertebrata, but which here rather deserve the name of circular, seeing that each forms a complete circle; of these the anterior and the middle are joined together at their commencement by the wide intercommunicating branch which opens through the intervention of a small membranous tube into the anterior small sac of the vestibule. The third or posterior canal communicates with the large sac of the vestibule by means of a wide canal, but has no direct communication with either of the others.

Each circular canal has a dilated portion or ampulla near one of its extremities, and is filled with a pellucid viscid fluid. They are all contained in cartilaginous tubes excavated in the cartilaginous substance of the cranium, but much wider than the membranous canals themselves, the latter being suspended in a fluid interposed between them and the perichondrial lining of the cartilaginous passages, to which they are fixed by a delicate cellulosity, in which slender vessels and very minute nerves are visible.

The auditory nerve on entering the ear divides into several branches. Of these the principal spreads out upon the inferior aspect of the great sac of the vestibule, where it forms a rich plexus; a similar but smaller plexus is formed upon the smaller anterior sac communicating with the vestibule, while the other branches are appropriated to the semicircular canals, on the ampullæ of which they would seem to be exclusively distributed; at least after forming a very beautiful expansion upon the dilated portion of the canal, it is impossible, owing perhaps to their very minute size, to trace them any further over its cylindrical part.

Generative system.—One of the most remarkable circumstances connected with the history of the finny tribes is their extreme fertility, which, compared with that of the higher Vertebrata, is truly prodigious. A codfish has been calculated to produce 9,000,000 of eggs in a single season, and innumerable races of the osteopteryginous Fishes exhibit powers of reproduction equally extraordinary. To imagine that this exuberant fecundity is destined merely for the purpose of perpetuating the species would evidently be preposterous, and we are necessarily led to look for other reasons explanatory of such teeming births. There is this leading difference between the terrestrial and aquatic domains of animated nature—the earth is inhabited only at its surface, and the vegetable banquet which is there spread out in such rich abundance is sufficient to afford the means of subsistence to all earth's progeny. But the sea, throughout all its depth, at every altitude which man has been able to explore, is peopled with innumerable races of voracious beings, all of which are necessarily dependent for their existence upon a supply of animal food, which must consequently be distributed as widely as the waves of ocean are diffused. It is to supply this great stock of living provender that the Sponges and the Polyps and all the humbler marine forms of existence are continually pouring forth their multitudinous germs, and it is for the purpose of adding to this enormous store that the majority of the osseous Fishes are so inordinately prolific.

From these considerations we perceive at once a reason for the extraordinary apathy and total absence of parental affection which forms so conspicuous a feature in the character of the whole race, and it is by no means a subject devoid of interest to observe how gradually the ties between parent and offspring are drawn closer and closer as we ascend from these humblest members of the Vertebrata and arrive at progressively increasing intelligence as we advance from class to class.

The generative apparatus of Fishes, as we have pointed out in a preceding article, (GENERATION, ORGANS OF, Comp. Anat.,) pre-

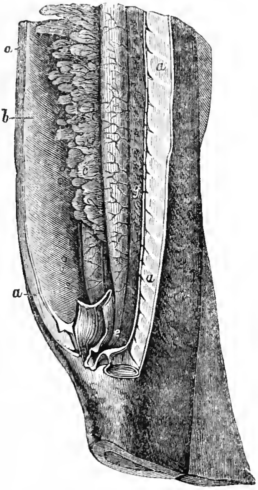
* Weber, loco cit.

sents itself under three principal types, each of which will merit distinct consideration.

The first is that observed in the DermapterygINOUS or Cyclostomatous Fishes, such as the Myxine and Lamprey; but it is not peculiar to this group, seeing that the Eels and perhaps other races have a similar organization.

On opening the abdomen of one of these Fishes, as, for example, the Lamprey, (*Petromyzon marinus*, *fig.* 534) an exceedingly

Fig. 534.

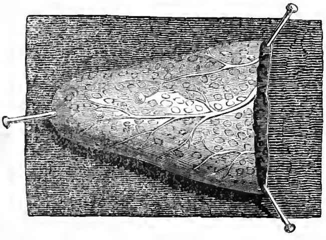


Female generative organs of the Lamprey (Petromyzon marinus).

a, parietes of abdomen; *b*, cavity of ditto; *c*, ovary; *e*, external passage leading into abdominal cavity, through which the ova are discharged; *g*, kidney.

extensive membranous expansion is found suspended in loose folds, which is attached by a kind of mesentery beneath the spinal column, and extending along the whole length of the abdominal cavity. Except in the breeding

Fig. 535.



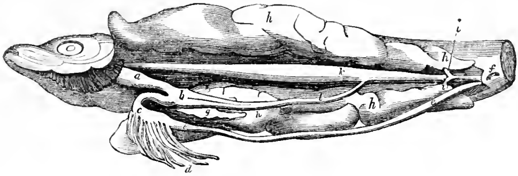
One of the folds of the ovary of the Lamprey, (Petromyzon marinus,) showing the enclosed ova.

season, this membrane, of which a portion only is represented in the figure, (*fig.* 534, *c*,) is thin and transparent, but at the same time exhibits considerable vascularity. When the breeding season approaches, innumerable granules begin to make their appearance, between the two layers of which this expansion consists, which in the female soon proclaim themselves to be ova (*fig.* 535), and, as they increase in size, gradually distend the whole abdomen. On opening the fish in this condition the abdominal cavity appears to be completely filled with innumerable ova beautifully arranged in rich festoons, all of which are connected in front of the spinal column. When the ova are quite mature they are cast loose from the ovary and escape from the ovarian membrane in which they were formed, into the general cavity of the abdomen, wherein they may be found at this period floating quite loose preparatory to their expulsion. This is ultimately effected through a simple but wide orifice (*e*) situated immediately behind the anal aperture, and causing a free communication to exist between the peritoneal cavity and the exterior of the body, so that the ova easily pass out and are ejected into the surrounding water.

In the males of those Fishes which offer this type of the generative system the appearance of the reproductive organ is, while in a state of inactivity, so exactly similar to that of the female as to preclude the possibility of distinguishing the two from each other; but, as the breeding season advances, the difference becomes apparent; the festooned membrane, which must in this case be called the *testis*, secretes a kind of milt or seminal fluid, rich in seminal animalcules, which in the same manner as the ova of the female escapes into the peritoneal cavity and is expelled through a postanal orifice to be diffused through the surrounding water, by the agency of which it is applied to the previously deposited spawn of the female, whose ova thus becoming vivified are left to the mercy of circumstances to be destroyed or hatched in due season.

In the second form of the generative apparatus which is common to almost all the true osseous Fishes, a very different arrangement is met with. The folds of the ovarian membrane, instead of being loosely suspended in the abdominal cavity, are now completely enclosed in two capacious membranous capsules, situated one on each side of the spine, and which when distended with ova occupy a very large share of the abdomen. On opening one of these capsules, the ova which it contains are seen, however, to be developed between the two layers of the proper ovary, exactly as in the case of the Lamprey, and to be attached in broad festoons to the interior of its walls, the essential difference being that whereas in the preceding type the eggs, when expelled from the ovary, escaped into the peritoneal sac, they now are retained by the capsular envelope of the ovary, whence they are expelled through excretory canals provided for the purpose. These, as they exist in the Herring, are represented in the annexed figure (*fig.* 536); from the posterior extremity of each

Fig. 536.



Viscera of the Herring (Clupea harengus).

a, œsophagus ; ***b, c,*** stomach ; ***d,*** pyloric cœca ; ***e,*** intestine ; ***f,*** anus ; ***g,*** spleen ; ***h, h,*** ovary ; ***i,*** oviducts ; ***k,*** air-bladder.

ovarian capsule arises a short canal *i, i*, and these two ducts uniting form a common tube, through which the ova pass out of the body through an aperture, *f*, situated immediately behind the anus.

In the male the disposition of the generative organs is precisely similar, the membrane contained in the two capsules secreting *milt* instead of *spawn*, which when expelled through the efferent duct and thus mixed with the water in the vicinity of the ova of the female, previously deposited, impregnates them by aspersion. Instances are recorded by Cavolini and others of a remarkable kind of hermaphrodism occasionally met with in Fishes presenting this type of structure, in which, while the generative capsule upon one side of the body contained a roe-secreting membrane, that of the other furnished milt, so that one half of the fish was male and the other female; such an arrangement, however, can only be looked upon as a lusus naturæ, although regarded by some of the older naturalists as a normal occurrence.

Among the Salmonidæ a very interesting arrangement of the generative apparatus is met with, which would seem to offer an intermediate condition between that of the Lamprey and that of the ordinary osseous Fishes. In the Trout and Salmon for instance, the extensive folds of the ovarian membrane are only partially enclosed in an investing capsule, the interior of which communicates by means of a wide slit with the abdominal cavity. In the common Salmon (Salmo Salar, Linn.) the ovary is much reduced in its relative size when compared with that of the Lamprey or of the Eel, although the ova are still developed in the folds of an irregularly transversely plaited membrane. These folds and their contained ova are, however, enveloped on their posterior and lateral aspects by a thin capsule, which is wanting on their anterior surface. Through this anterior opening in the capsule the ova are discharged into the cavity of the abdomen, whence they are finally expelled through the peritoneal apertures situated near the anus, as in the Lamprey.

Notwithstanding that the great majority of the osseous Fishes shed their spawn to be impregnated out of the body, some rare instances are met with in which the females are viviparous, producing their offspring not only already hatched, but even considerably advanced in growth. Such, for example, is the Viviparous Blenny. In cases such as these it is evident that impregnation must occur internally, and accordingly a kind of copulation must be presumed to be effected. Yet, even in these Fishes no very obvious peculiarity is to be detected in the structure either of the male or female organs; neither is the male better provided with an intromittent apparatus than the ordinary oviparous genera.

The *Syngnathidæ*, or pipe-fishes, offer a very peculiar conformation, which is not inaptly comparable to what is met with among the marsupial Mammalia, namely, a pouch wherein the ova are carried about until after they are hatched, and in which the young are defended during the earliest period of their growth.

In the plagiostome cartilaginous Fishes the arrangement of the generative apparatus of both sexes is of a very different character, approximating that type of structure which is common to the Reptilia and Birds. In the male Shark (Squalus acanthias), which may be taken as an example of the group, the anatomy of these parts is as follows. The testes, two in number, (for the minute structure of which the reader is referred to our preceding article Generation, organs of, Comp. Anat.) are situated at the anterior part of the abdomen, on each side of the mesial line, (*fig.* 537, *k,*) where they are attached by their inner margins to a duplicature of the peritoneum, which connects them with the region of the spine. The vasa deferentia derived from each of these glands are long and tortuous tubes *(l, l,)*, increasing in size as they pass backwards towards the cloaca, into which they open by an orifice common to them and to the ureters upon a kind of papillary eminence *(o)*, which is here in truth a rudimentary penis adapted to facilitate the impregnation of the female which takes place internally.

The openings communicating between the cloaca and the cavity of the peritoneum *(fig.* 537, *p, p,*) are situated a little lower down beneath a kind of valvular fold formed by the termination of the rectum.

In the vicinity of the cloacal aperture are situated the claspers, or holders, *(q, q,)* so called because they are generally supposed to be used for clasping or holding the female during the sexual intercourse necessary for internal impregnation, although some authors have imagined them rather to perform the office of an intromittent organ by being actually in-

Fig. 537.

a, heart; *b*, liver; *c*, œsophagus; *d*, stomach; *e*, pyloric portion of stomach; *g*, pancreas; *h*, *i*, intestine; *k*, testis; *l*, vas deferens; *m*, urinary bladder; *o*, rudimental penis; *p*, *p*, peritoneal openings; *q*, *q*, claspers.

troduced into the cloaca of the other sex in the act of impregnation. The following is Cuvier's description of these remarkable organs, which are met with in the males both of the Sharks and Rays and likewise of the Chimæræ, and from the composition and relations of the cartilages and muscle which enter into their structure are evidently only an extension or appendage of the ventral fins. They consist in the Rays and Skates of two cartilages articulated end to end, situated along the inner side, which forms the basis of the whole apparatus. The first of these cartilages, which is a sort of *femur*, articulates with the pelvis, and supports, in conjunction with the second (the *tibia*), the rays of the ventral fin.

A third cartilage unites this fin with the genital portion like a kind of astragalus; this articulates with the longest cartilage of the limb.

On the side of the astragalus is an oval cartilage having a sharp inferior margin, to which may be applied the name of *os calcis*.

The os calcis articulates posteriorly with another principal piece of the limb which may be called the *metatarsus*. This extends all along the upper and inner border of the limb as far as its extremity, where it forms a sort of digit, to which is attached the tendon of the great abductor muscle. This large piece is formed by the consolidation of three smaller ones, two of which run parallel to each other, so as to constitute a semi-canal, into which opens a duct derived from a large gland hereafter to be described.

To the metatarsus succeed seven other cartilages, the shape of which is different in the various species of Chondropterygii, but which obviously represent the phalanges of the abdominal limb, which is moved by five strong muscles which may be named respectively the depressor, the elevator, the abductor, the adductor, and the expansor of the fin. It is, however, remarkable that there is no muscular apparatus calculated to approximate these members, and when separated they are brought together again entirely by their own elasticity, a circumstance which militates strongly against their being, as is generally supposed, instruments of prehension. In the Sharks the clasper contains morever a gland of considerable size situated beneath the fin, and extending to the exterior of the base of its genital appendage. Inferiorly, this gland is only covered by the skin, while above it is adherent by the intervention of cellular tissue to the rays of the fin. Its duct is a wide canal which opens into the groove formed by the metatarsal cartilages above alluded to, and the fluid which it secretes of a highly viscid character. It is said that in the breeding season the contents of this gland, as well as the parietes of the cavity in which it is situated, are red with blood and appear to be in a remarkable state of turgescence. It is enclosed in a double tunic, one fibrous and the other muscular, by the assistance of the latter of which its contents are evacuated.

At the lower extremity of this gland, near its orifice, there is in each clasper a capsule with muscular and cavernous parietes, the cavity of which is traversed by slender tendinous filaments. In these sacs Dr. John Davy* has observed distinct pulsations, and finding that in the living fish they were filled with blood, considers them as accessory hearts destined to assist the circulation of the blood in these appendages to the genital system.

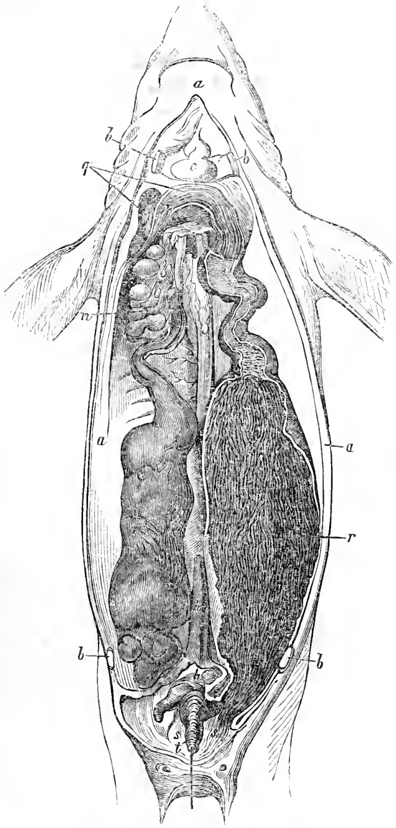
The gland itself is of the shape of an olive; a longitudinal sulcus divides it into two portions, in each of which a transverse series of very delicate tubes is distinguishable.

In the females of the Plagiostome Chondropterygii the arrangement of the sexual organs conforms in an equally striking manner with the Reptilian type of structure. The

* Phil. Trans. 1839.

ovary is distinct from the oviduct, as in the three higher classes of Vertebrata. When the ovules are not developed,* the ovary of the *Sharks* forms a thick oval lamina slightly notched or concave upon its inner border, suspended upon each side of the vertebral column at the very anterior extremity of the abdominal cavity, from which point it is prolonged backwards for a greater or less extent. The inferior and internal surface of this lamina, that by which the ovaria would touch each other if approximated, presents no prominences, but is of a uniform milk-white colour. The posterior surface of the organ has the same appearance, except that upon the anterior half or two-thirds of the ovary little rounded eminences of different sizes are perceptible, the smallest of which are pearl-white, while the larger are of an opaque-yellow colour; these are the ovules in process of developement from the proligerous stratum of the ovary, which gradually increase in size as they advance towards maturity, and project through the upper surface of the ovary. This latter expands itself in the form of a capsule over the ovules in such a manner that as their developement increases they become detached from each other, and separating themselves more and more become at length racemose.

Fig. 538.



Viscera of female Shark, after Hunter.

The remainder of the ovarian lamina retains its soft, milky, homogeneous appearance, which is very characteristic, and resembles very closely one portion of the testis of the male.

In many of the viviparous Sharks, that portion of the ovary only which does not form eggs is met with upon one (generally the left) side of the body, whilst upon the opposite the organ attains its full developement.

The general disposition of the rest of the generative apparatus is well shewn in the accompanying figure (*fig.* 538) of the sexual organs of the female Dog-fish, (*Spinax acanthias*, Cuv.,) taken from one of the admirable drawings left by John Hunter, and engraved in the Catalogue of the Hunterian Museum.

The ovary (*n*) presents ovisacs in different stages of developement attached by a duplicature of peritoneum to the side of the spine, immediately below the liver and œsophagus. The anterior orifices of the oviducts (*q*, *q*) are situated close together above the liver; their coats, which are at first thin and membranous, gradually increase in thickness, and about four inches from the orifice become suddenly thickened by the addition of a laminated glandular structure; this is, however, much less developed in the present viviparous species than in the oviparous cartilaginous Fishes, and the size of the oviduct continued from the glandular part more nearly corresponds with that of the preceding portion than in the oviparous races. Beyond the glandular portion the oviduct gradually increases in diameter, having its lining membrane thrown into longitudinal plicæ, until suddenly it dilates into a wide uterine portion (*r*), in which, in the viviparous Sharks, the young are retained after the eggs are hatched, until they are fit for exclusion in a living state.

In the dilated uterine portion the lining membrane is gathered in close longitudinal folds, and their free margins, which are beautifully wavy, contain each a vessel, which follows the sinuosities of the fold, and sends off branches to the parietes of the oviduct. Towards the terminations of the oviducts

* Cuvier, Leçons d'Anatomie Comparée, tom. viii. 1846.

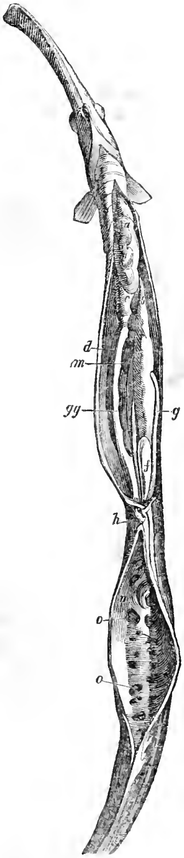
in the cloacal cavity (*s, s*), these folds gradually subside into a few simple plications.

In some species (*Mustelus, Cuv.*) of these viviparous Sharks a very close attachment is formed between the walls of the uterine portion of the oviduct and the contained ovum, so much so indeed as to remind the anatomist very forcibly of the placental connection that exists in the Mammifera. In these, according to J. Müller, the ovum, on its arrival in the oviduct, is only covered with a kind of membranous investment or chorion, which is as thin and delicate as the amnion of Mammalia, and without apparent organization. The sac which this membrane forms is seven or eight times as long as the vitellus, and its walls being regularly plicated, are embraced by corresponding folds of the lining membrane of the oviduct, so that there is a very intimate adhesion between the two.

In the oviparous races of the plagiostome cartilaginous Fishes the structure of the oviduct is somewhat different, in order to provide for the formation of the egg-shell or horny envelope wherein the egg is contained when extruded from the body, the organization of which is not a little curious. The glandular portion of the oviduct is extremely thick, or rather is enclosed in a dense glandular mass (*rudimental gland*), the substance of which is entirely made up of close-set transverse secerning tubes, which pour their secretion into the oviduct through innumerable orifices, which are aggregated together in a part where the course of the lining membrane of the oviducal canal is interrupted, and free passage thus left for the escape of the rudimental secretion, which, becoming thus deposited on the surface of the egg, hardens into a tough horny substance, which constitutes its external covering or egg-shell. The shape of these eggs is remarkable; the egg-shell when completed resembles an oblong horny pillow-case, the four corners of which are prolonged into tendril-like processes, the use of which appears to be that they serve as anchors by becoming interlaced with the branches of submarine plants or ramose corals, and thus preserve the egg and its delicate contents from being washed away by the agitation of the waves. From the tough coriaceous or horny texture of these egg-shells, another provision becomes necessary, in order that the mature embryo shall be enabled to escape from confinement and enter upon an independent existence. In the eggs of Birds this is abundantly provided for by the brittle texture of the calcareous substance in which they are enclosed, allowing the chick to break its way out of its fragile covering, a mode of egress which, in the case before us, would evidently be impracticable. This difficulty is met by a very beautiful contrivance. The horny walls of the eggs of the plagiostome Fishes are continuous all round, except at one extremity, where, to use a homely illustration, the end of the pillow-case remains unsewn, the edges of the slit thus left being merely kept in apposition by the elasticity of the horny envelope. By this elegant arrangement all intrusion from without is effectually prevented, and at the same time, seeing that the valves will separate on the application of a very slight pressure from within, they soon yield to the efforts of the young fish to escape from its cradle, and afterwards close again so accurately that it is difficult, without attentive examination, to detect the existence of the fissure.

As amongst mammiferous animals certain races are provided with a marsupium or pouch, in which their immature young are carried about for a considerable period previous to their birth, so do we find certain Fishes provided

Fig. 539.



Viscera of Syngnathus acus (male).

a, liver; *b*, communication between the swimming bladder and the alimentary canal; *c*, stomach; *d*, intestine; *f*, allantoid bladder; *g, gg*, testes; *m*, kidney; *n*, marsupial pouch; *o, o*, cells in interior of ditto.

with a similar marsupial apparatus, in which the eggs are hatched and the young permitted to arrive at their full developement prior to their expulsion. These are the *Syngnathidæ*, or pipe-fishes. There is, however, this remarkable difference between the mammiferous marsupials and these singularly organized genera, namely, that in the former it is the female that is furnished with the marsupial pouch, whereas in the Syngnathidæ the male only is so provided. In *fig.* 539, representing the male of *Syngnathus acus*, the marsupial apparatus is well exhibited; it consists of two large valves (*n*) situated beneath the tail, immediately posterior to the cloacal orifice. The internal surface of this pouch is indented with deep cells (*o*, *o*), more especially towards its posterior surface, where the ova are principally lodged. Here the eggs are hatched, after which the young *Syngnathi* are retained in the pouch for a considerable period before they are finally expelled.

In the female Syngnathus there is no subcaudal pouch developed, but in this sex the vulva is unusually prominent, apparently for the purpose of facilitating the conveyance of the ova into the marsupium of the male.

In *Syngnathus ophidion* (Bloch) the ova, after extrusion from the female and impregnation, become attached to the cellular surface of the ventral parietes of the abdomen of the male, but are not protected by cutaneous processes or valves.

Urinary apparatus.—The kidneys in Fishes, as in all other Vertebrata, are two in number, situated on each side of the spine. They are, however, in the class before us remarkable for their very great proportionate size, sometimes extending from the anterior boundary of the abdomen quite to its posterior extremity, and occasionally uniting together in the mesial plane, so as to have the appearance of being but a single gland. Internally they present no division into cortex and fasciculate ducts terminating in a pelvic cavity, but their parenchyma is homogeneous, being entirely composed of arborescent ducts, which are immediately continuous with the ureters, which, running along the anterior surface of the kidney, receive the uriniferous tubes as they pass along towards the cloaca, where they terminate. Most commonly there is a distinct urinary or allantoid bladder situated behind or dorsad to the rectum (*fig.* 539, *f*), which, in some species, is bifid at the anterior extremity, as in the Frog and other amphibia.

Occasionally the urinary canals unite and terminate by a common duct (*ureter*) upon a fleshy tubercle or penis-like projection of the walls of the cloaca, as in the female Shark (*fig.* 538, *t*), where a bristle is represented introduced into the extremity of the urinary passage.

Renal capsules.—In the osseous Fishes these organs are supposed to be represented by two or sometimes three roundish bodies of a light grey colour, situated sometimes near the middle, oftener at the hinder extremities of the kidneys, at or near the entry of the hœmal canal; sometimes they lie free, sometimes they are imbedded in the renal tissue (Pike, Salmon, Eel); but they always possess a proper capsule and present a minutely granular texture without distinction of cortical and medullary parts.* In the yellowish suprarenal bodies of the Sturgeon, the granules are minute spherical cells filled by microscopic nucleated corpuscles. In the Plagiostomes they are represented by elongated narrow yellowish bodies situated behind the kidneys, and sometimes extending behind the dilated ureters.
